JANUARY 1949

### RESULTS OF THERAPY OF ERYTHROBLASTOSIS WITH EXCHANGE TRANSFUSION

By ALEXANDER S WIENER, M D , AND IRVING B WEXLER M D

IN PREVIOUS papers<sup>1 2 3 4</sup> we described the method of treatment of erythroblastosis fetalis with exchange transfusion and presented a few illustrative cases in detail. The purpose of the present paper is to summarize our results in the first 28 cases.

The rationale of the therapy of erythroblastosis by exchange transfusion can be briefly outlined as follows. According to our concept<sup>5 6 7</sup> of the pathogenesis of the disease, in the typical case the Rh-positive erythroblastotic baby is born with its red cells coated with univalent Rh antibodies, derived from the mother during intrauterine life by transplacental filtration. In some cases, it is possible that additional Rh antibodies of the bivalent type (agglutinins) may be milked into the fetal circulation by the uterine contractions occurring during labor. In any event, the antibodies acting on the infant's red cells may cause them to hemolyze or to clump (by agglutination or conglutination). In cases in which only hemolysis occurs, a hemolytic anemia results which responds to simple transfusions of Rh-negative blood. If intravascular clumping takes place, on the other hand, the circulation to vital organs may become compromised producing the picture of icterus gravis, often terminating with the death of the infant with the postmortem findings of nuclear jaundice and hepatic necrosis. Obviously, such cases will not be benefited by simple transfusion since such therapy cannot reverse the process of red cell clumping. Luckily, intravascular clumping, when it occurs, probably takes place to greatest extent after birth, because *in utero* the conglutinin content of the fetal plasma is low.<sup>8 9 10</sup> We believe that with the birth of the infant, the conglutinin content may rise to a concentration sufficient to cause clumping of the red cells. The clumping, at first, may be thought of as reversible, the red cells behaving as if they were sticky (sludged blood, Knisely<sup>11</sup>), but in untreated cases, it is probable that the clumping eventually becomes firm, blocking the circulation. If, during the early stages of the disease the infant's blood is drained off and simultaneously replaced with type rh blood of a compatible blood group, it is likely that the disease will become aborted, because type rh blood cells cannot be clumped by the Rh antibodies in the baby's body.

From the Blood Transfusion Division and the Department of Pediatrics of the Jewish Hospital of Brooklyn N Y and from the Serological Laboratory of the Office of the Chief Medical Examiner of New York City

Obviously, in doing exchange transfusions the process of bleeding and infusion must be carried out simultaneously. Thus, the operation becomes progressively less efficient, because as it proceeds, more and more of the donor's blood, and less and less of the infant's blood is withdrawn, so that a complete replacement of blood is theoretically impossible. For practical reasons, it was first decided to limit the exchange to 500 cc. of blood, or about twice the infant's blood volume, and thus effectuate an 87 per cent replacement.<sup>1, 2</sup> It was subsequently found that while this was adequate in the great majority of cases, in more severe cases the remaining 13 per cent of the infant's coated red cells apparently clumped instead of lysing and thus nullified the beneficial effects of the procedure. More recently, therefore, we have modified the procedure, particularly in cases with high antibody titers, by using 1,000 cc. of blood and thus effectuating a 98 per cent replacement.<sup>3</sup> In addition, as our experience has increased, other, less vital, changes have been introduced, calculated to simplify and expedite the operation. In the present paper, with but a single exception (case 10b), only those cases are presented in which 500 cc. of blood were used for the exchange transfusion. In a later paper it is intended to present a second series of cases, for comparison, in which 1,000 cc. exchange transfusions were performed.

#### ANTENATAL MANAGEMENT OF CASES

All pregnant women should be screened to determine if they are Rh positive or Rh negative. Grouping and Rh-Hr typing are done on the husband and all living children of those pregnant women found to be Rh negative, and information obtained as to whether the husband, if Rh positive, is homozygous or heterozygous.<sup>4</sup> In certain instances, the husband's parents must be tested to obtain this important information. Since, when the maternal serum contains univalent Rh antibodies, the severity of the disease usually bears a direct relationship to the titer,<sup>7, 10, 13</sup> the maternal serum is tested at intervals throughout the pregnancy for the presence and titer of antibodies by the saline agglutination and albumin-plasma conglutination techniques.<sup>14</sup>

On the basis of information obtained from these studies, decisions can be made regarding the time of delivery of the infant and the treatment to be instituted after birth. Women who show no sensitization will, of course, be permitted to go to term because their infants will not be erythroblastotic. Mildly sensitized\* women are delivered at term and the infant is treated expectantly and watched for the development of anemia, jaundice, or other signs of erythroblastosis. In those cases where moderate sensitization has developed, the infant is delivered about two weeks before term and treated with immediate exchange transfusion, using 500 cc.

\* Since the same sera in the hands of different workers yield different values each worker must determine for himself what values to describe as low moderate high and lethal. In our laboratory based on our experiences described in this paper the following arbitrary limits have served as our guide: low less than 5 units moderate between 5 and 20 units high, between 20 and 50 units, lethal, above 50 units. This applies only to titers of univalent antibodies by the plasma albumin conglutination method, when the saline titration shows no agglutinin to be present. As will be explained later, in the presence of agglutinins the commonly available methods do not permit a clear-cut identification of univalent antibodies. (Cf. however the recent paper of Wiener and Handman<sup>15</sup>)

of donor's blood for the procedure. More severely sensitized women may even be delivered somewhat earlier and the infant treated by immediate exchange transfusion, using about 1,000 cc. of blood. With very high titers the fetus usually fails to survive until the period of viability, and the resultant dead fetuses are permitted to deliver spontaneously or are aborted.

### RH TYPING AND ANTIBODY TESTS

The bloods of all individuals in each family were classified as to blood group and subgroup, M-N type and Rh-Hr type. The blood grouping and M-N tests were done by the well slide agglutination technic while the Rh-Hr tests were done by the tube agglutination technic. The Rh antisera were obtained in part from male Rh negative donors who had been immunized by injections of Rh positive blood and in part from Rh negative mothers of erythroblastotic infants who, after sterilization, were given stimulating doses of Rh positive blood. While the anti-Rh<sub>0</sub> serum used was a pure agglutinating serum, the anti-rh' and the anti-rh" sera had been prepared from sera of specificity anti-Rh<sub>0</sub> and anti-Rh<sub>0'</sub> by the addition of anti-Rh<sub>0</sub> blocking serum. Anti-hr' serum was available from a type Rh<sub>1</sub>Rh<sub>1</sub> woman who had had an erythroblastotic infant and a small amount of anti-hr" serum had been kindly provided by Dr. A. E. Mourant.

The Rh antibody content of the expectant mother's serum was determined when possible at monthly intervals or more frequently according to the indications by the saline agglutination, albumin plasma conglutination, and at times by the blocking technic. For these titrations fresh suspensions of type Rh<sub>1</sub>, type Rh<sub>2</sub>, and type rh cells were prepared from oxalated group O blood which had been freshly drawn from the vein or stored no longer than seventy-two hours in the refrigerator. All suspensions were washed once by centrifuging, decanting the supernatant, and resuspending the cells in fresh saline to produce a 2 per cent suspension in terms of blood sediment. As mentioned in previous papers, the most common error in the titration technic is in preparing the serum dilutions. Improper rinsing results in carrying over, and accounts for the extraordinarily high titers sometimes reported in the literature. The proper precautions to be followed have been described in previous papers and will not be repeated here. The individual titration technics were carried out as follows:

**Agglutination method.** One drop each of progressively doubled dilutions of the maternal serum was transferred to a series of small test tubes (8 mm. diameter) and to each tube was then added a drop of the test blood suspension. The mixtures were shaken and the rack was placed in the water bath or incubator at 37°C. for one hour. The tubes were then gently tilted one by one in order to dislodge the sediment and the reactions were read under the low power of the microscope by placing the entire tube on the stage under the objective.\*

**Albumin-plasma conglutination method.** A duplicate titration was set up as described for the agglutination method. After the one hour incubation period when the cells had completely sedimented, the supernatant fluid was removed as completely as possible with a fine capillary pipet proceeding from the highest serum dilution to the most concentrated. Then to each tube was added a large drop of fresh albumin plasma mixture, prepared by mixing 4 parts of pooled oxalated plasma from Rh positive individuals with 1 part of 25 per cent human albumin or 30 per cent bovine albumin solution. The tubes were then vigorously shaken to resuspend the cells and were reincubated for another hour at body temperature. At the end of this time the tubes were individually shaken, somewhat more vigorously than for the agglutination technic, and the reactions read under the low power of the microscope.

**Blocking technic.** If the agglutination test was negative and the conglutination showed a significantly high titer, tests were usually carried out by the blocking technic. Again the first step was the titration by the saline agglutination method. Then to each tube was added one drop of an anti-Rh<sub>0</sub> agglutinating serum diluted with saline so as to have a titer of about 10 to 20 units. The mixtures were reincubated for one hour at 37°C. and then the tubes were gently shaken, one by one, and the reactions read under the microscope.

\* By removing the lower half of the ordinary low power objective one is left with a weaker objective which gives lower magnification and ample working space into which to place the test tube.

*Interpretation* For the sake of uniformity all readings were taken by the senior author. If he was out in the laboratory when the incubation period was over the racks were placed on the laboratory table at room temperature until his arrival but this did not seem to affect the results materially. During his absence from the laboratory his assistant read the reactions. The reactions were graded as +++ + + + ±, ++, + and -, where +++ represents one large clump of cells, while ++ and +, etc. progressively weaker reactions and - represents a uniform suspension with no clumps. In the agglutination and conglutination titrations the titer (in units) was taken as the reciprocal of the highest dilution giving a one plus reaction. In the blocking test the titer was taken as the reciprocal of the highest dilution causing complete or almost complete inhibition of agglutination. It was found that the freshness of the test cell suspensions had a more striking effect on the titers obtained than did the Rh type or the zygosity. For example with fresh cells the conglutination titer was usually 20 to 40 times as high as the blocking titer, however if the cells were old the conglutination titer would be lower and the blocking titer higher so that this pitfall could be recognized by a reduction in the ratio. When such abnormal results were obtained the tests were repeated with fresh cell suspensions and in this way mistakes were often avoided. The serologic titration method is crude as compared with chemical titrations and has a large intrinsic error. By performing the titrations with two different Rh positive cells (type Rh<sub>1</sub>rh and Rh<sub>2</sub>Rh<sub>2</sub> as a rule) and averaging the results this error was minimized. The titer values listed in our tables thus represent the average of at least two and usually more titrations.

Even with these precautions the results can be considered to have an intrinsic error of about one tube and this fact must be kept in mind when evaluating the significance of apparent titer fluctuations in tests done serially on any given patient's serum. For example, suppose it is desired to determine if the following series of titers shows any significant fluctuation: 17, 33, 40, 19, 36 and 50. The average of these six values is 33 units. A serum that actually has a titer of 33 units could in tests made at different times give titer values ranging from 16 to 66 units due to variations of technic without indicating that there has been any actual fluctuation in the degree of sensitization. On the other hand had the following values been obtained: 17, 33, 40, 19, 96, 80, 120 then one could assume that there had been a true rise in titer after the fourth sample was tested and that this rise was maintained during the last three tests. In any case of doubt the patient was recalled for another titration.

#### TECHNIC OF EXCHANGE TRANSFUSION\*

The exchange transfusion is carried out immediately after birth, using blood from a compatible, nonsensitized type rh donor. No time is wasted in carrying out conglutination or other serological tests, hemoglobin determinations, erythroblast counts, etc., although blood is taken for these studies. In the event, however, that the father is heterozygous the baby is tested in order to be certain that he or she is Rh positive before proceeding. In certain instances it is possible to predict from the groups of the parents what group of blood will be compatible with the infant's blood.<sup>4</sup> In such cases, the blood can be made available before the baby is born. Where this is not possible, nonsensitized type rh donors belonging to groups A, B, AB and O are kept standing by until the infant's blood group is determined.

The infant is immobilized on a circumcision board, and a 20 gage cannula is inserted into the saphenous vein at the ankle. The infusion of blood is started after the injection of 0.2 cc (200 units) of heparin intravenously. A three-way stopcock connects the tubing of the infusion to the cannula and makes it possible to inject medication as needed and to control the speed of the infusion. A period of fifteen minutes is permitted to elapse before the bleeding is started. This wait is important because it allows time for the heparin to exert its maximum effect and at the same

\* A motion picture demonstrating our technic of exchange transfusion is available to medical societies for loan upon application to the authors.

time permits about 50 cc of blood to enter the infant's circulation and produce enough of plethora to make the arteriotomy an easy procedure. The radial artery is exposed through an incision made just above the lower end of the radius, it is cleaned of all adventitial tissue and lifted up on a hemostat, and with a small scalpel a flap is cut into the artery by inserting the blade into the center of the artery and drawing it diagonally outward. The flow of blood is immediate and copious. The blood is collected in one ounce medicine glasses which are emptied into a graduated bottle. The inflow and outflow of blood are measured carefully and the infusion is kept running about 50 cc ahead of the bleeding at all times. This is easily accomplished by using a syringe on the three-way stopcock to inject the blood at an increased rate when necessary. When 250 cc of blood have run in, a second dose of heparin is given intravenously. No further heparin injections are given, so that by the time the procedure is completed the heparin effect is nullified. When an 1,000 cc exchange transfusion is performed the final dose of heparin is given after 500 cc of blood has been injected. A 10 cc syringe containing a 10 per cent calcium gluconate solution is kept on hand at all times during the procedure, and if signs or symptoms of hypocalcemia supervene, 5 cc are injected carefully directly through the cannula. As a rule, no calcium is required for transfusions of 500 cc or less, provided the transfusion is not given too rapidly, that is, within less than an hour. For larger exchange transfusions, it is best to inject 5 cc of calcium gluconate prophylactically at the 500 cc mark, even though the patient exhibits no untoward symptoms. In 500 cc exchange transfusions the amount of blood injected should exceed the amount withdrawn by about 50 cc, in the 1000 cc transfusions a margin of about 75 cc should be allowed. In infants severely anemic at birth this margin should be increased by another 50 cc.<sup>15</sup> At the close of the procedure the radial artery is usually tied off before closing the incision at the wrist, but a snug bandage will control any venous oozing from the incision at the ankle. A small amount of sulfadiazine powder is placed into the wounds before closing them, and the infant is routinely given 20,000 units of penicillin intramuscularly every three hours for twenty-four hours after the operation. Subsequent treatment of the infant is routine, except that breast feeding is interdicted.

### RESULTS

For the purpose of evaluating the efficacy of the treatment, the cases have been divided into four categories as follows:

- (1) Severe cases, with recovery, (2) fatal cases, (3) cases of moderate severity, and (4) mild cases.

#### *Severe Cases, with Recovery*

CASE 1.—This case has been presented in detail elsewhere<sup>2</sup> and to conserve space will not be repeated here. It is however included in the discussion at the end of this paper.

CASE 2.—This patient was referred to us twenty-four hours after birth. He was the product of the second pregnancy, the first and only previous pregnancy having been normal. The mother had never received any blood transfusions. The infant was jaundiced at birth and the splenic edge was palpable 3 fingerbreadths below the costal margin. After several hours an anemia of 8.8 grams per cent of hemoglobin was found with a red blood count of 3.71 million red blood cells per cu mm. The uncorrected

white blood count was 64,000 cells and there were 296 normoblasts per 100 white blood cells on the smear. Anisocytosis and poikilocytosis were present to a marked degree.

*Findings:* Grouping and Rh Hr tests done on the family are shown in table 1.

Antibody studies done on the mother's plasma by the agglutination technic showed the presence of Rh antibodies of a titer of 20 units, while the titer of the Rh antibodies was 30 units by the plasma conglutination test and 70 units by the albumin plasma conglutination technic.\* The conglutination test for coating of the infant's red cells by univalent antibodies was positive.

*Prognosis:* The findings in this case pointed to a serious prognosis, namely the high titer of Rh antibodies in the maternal serum, the infant's deep jaundice, severe anemia, unusually high erythroblastemia as well as its poor clinical condition.

*Procedure:* At the start of the exchange transfusion the infant appeared to be in a condition bordering on shock. A subconjunctival hemorrhage was present in the left eye and small petechiae had appeared on the forehead. The skin had a mottled appearance and there were occasional nystagmoid movements of the eyes. The exchange transfusion was performed using blood from a donor who belonged to type OMNrh. In order to reduce the conglutinin content, the donor's blood was first treated by removing half of the plasma and replacing it with normal saline solution. Of this mixture, 560 cc. were injected while 500 cc. of blood were simultaneously withdrawn.

TABLE 1

Blood of	Group and subgroup	H N type	Rh-Hr type	
			Phenotype	Genotype
Father	B	N	Rh <sub>1</sub> Rh <sub>1</sub>	R <sup>1</sup> R <sup>1</sup> or R <sup>1</sup> r'
Mother	O	MN	rh	rr
1st son	O	MN	Rh <sub>1</sub> rh	R <sup>1</sup> r
Patient	O	MN	Rh <sub>1</sub> rh	R <sup>1</sup> r

\* The M N tests are not clinically important but are included for the sake of completeness.

*Results:* The immediate response was most dramatic. The infant appeared to be more vigorous and although there was no change in the jaundice the color and circulation were definitely improved. The hemoglobin on the day following the transfusion was 11.7 grams per cent and then rose to 13.2 grams. Jaundice became intense by the fifth day at which time the icterus index had risen to 120 units. During this time the baby was irritable and took his feeding poorly. By the sixth day marked clinical improvement was noted. The jaundice began to fade the petechiae noted on the forehead had been completely absorbed and from that time onward the baby acted well. The hemoglobin concentration continued to decrease over a period of a month when it reached a concentration of 6.6 grams per cent with a red blood count of 2.5 million per 100 mm. By this time the icterus had faded completely. The infant was given a transfusion of 70 cc. of O rh blood on the following day and the hemoglobin concentration rose to 9.2 grams. This child has been followed carefully for more than a year. Both his physical and mental progress had shown no deviation from the normal. He sat at five months and stood at 11 months. At one year he was beginning to take his first steps. His first four teeth have a greenish discoloration.

*CASE 3:*—This patient had had five miscarriages at 3 to 5 months over a period of three years. Her sixth pregnancy yielded a full term infant who is normal and well. This child showed no jaundice or anemia during her neonatal period. When first seen by us the mother was in the 32nd week of her seventh pregnancy and had been found to be Rh negative.

*Findings:* Groupings and Rh Hr tests done on the family are shown in table 2.

Antibody tests for Rh sensitization done on the mother's serum at this time showed agglutinins to be present in a titer of 7 units, while the titer was 16 units by the plasma conglutination technic. One month

\* The figures for antibody titers given in this paper represent averages of the results of at least two titrations.<sup>12, 14</sup>

later, the agglutinin titer was still 7 units, while the titer by the plasma conglutination technic was 20 units (This difference is not significant because it is within the limits of accuracy of the method of titration)

**Prognosis** This woman, then, was moderately sensitized to the Rh factor, and since the husband was most likely homozygous for Rb<sub>0</sub>, an Rh<sub>1</sub>rh or Rh rh infant could be expected who would have erythroblastosis in a severe form, and might even be stillborn if carried to term

**Procedure** Labor was induced in the thirty-eighth week of the pregnancy. Plans had been made to do an exchange transfusion immediately after birth, but the baby was born in a city many miles away and nine hours elapsed before we arrived at the hospital. In the meantime the infant had been found to have a hemoglobin of only 9.7 grams per cent and there were 12 normoblasts per 100 white blood cells on the smear. The baby was given a transfusion of packed red cells from 100 cc of O, rh bank blood. Shortly thereafter, the infant became cyanotic and was placed in an incubator. Moderate jaundice as well as cyanosis and difficulty in respiration were present when we saw the child. A few râles were present, scattered throughout both lung fields, which were interpreted as due to atelectasis. Although the transfusion had raised the hemoglobin concentration to 13.6 grams, an exchange transfusion was carried out with the administration of 560 cc of blood (half of the plasma in this blood was replaced by saline solution) and the simultaneous removal of 600 cc of blood. During the procedure the infant required repeated aspiration of mucus and inhalation of oxygen because of several episodes of cyanosis. In tests carried out later, the cord blood of the baby typed as OMRb<sub>2</sub> and the icterus index was 40 units.

TABLE 2

Blood of	Group and subgroup	M N type	Rh Hr type	
			Phenotype	Genotype
Father	O	M	Rh <sub>1</sub> Rh <sub>2</sub>	R <sup>1</sup> R <sup>2</sup> or R <sup>1</sup> r <sup>2</sup>
Mother	O	M	rh	rr
Daughter	O	M	Rb <sub>1</sub> rh	R <sup>1</sup> r

**Results** Differential agglutination studies showed that the combined procedures had left only 2 per cent of the infant's own blood cells in its circulation. The hemoglobin concentration of the blood was 11.6 grams per cent on the day following the transfusion and the child was clinically very much improved. The infant remained well, but the hemoglobin concentration fell gradually and on the fourteenth day of life another transfusion of 75 cc of Rh negative blood was given. From this point on the baby did very well. This child has been followed with great care for about a year and has been unusually healthy as well as having showed rather precocious advancement from the developmental point of view.

CASE 4—This case has already been reported in detail elsewhere.<sup>4</sup>

CASE 5—The mother of this patient was first seen by us in the twelfth week of her third pregnancy. Her first pregnancy terminated with the birth of a normal female who is well. Her second pregnancy was attended by a midwife, labor lasted two days and yielded an apparently normal infant who was jaundiced for a few days and then seemed to recover. This baby was nursed for several days during the neonatal period. At the age of seven months the child was unable to hold up its head, had athetoid movements, followed light poorly, and had a vacuous expression.

**Findings** Grouping and Rh Hr tests done on the father, mother and both children are shown in table 3.

Antibody studies done on the mother's serum at intervals during her pregnancy are given in table 4.

At the time of the last test, titrations for alpha and beta antibodies were done since a possibility of double sensitization (to A as well as to Rh) existed. By the agglutination technic the anti A titer\* was 48 units while the Anti B titer was also 48 units. With the albumin plasma method the anti A titer was 160 units and the anti B titer was 48 units.

\* Using test cells of subgroup A.

*Prognosis* On the basis of these findings there appeared to be little doubt that the expected infant would be severely affected by the disease and might even be stillborn if the pregnancy were allowed to go to term. In addition to the harm that would be done by the univalent Rh antibodies, one might expect some injury to be caused by the alpha antibodies that were present if the baby proved to be group A.

*Procedure* Delivery was spontaneous at term. The infant appeared normal at birth and had a hemoglobin concentration of 15.5 grams per cent. The erythrocytes typed as  $A_2MNRh_1rh$  and were shown by the conglutination technic to be coated with univalent antibodies. Immediate exchange transfusion was carried out using blood from a group A, type rh donor from which one-half of the plasma had been removed and replaced with saline. Over a period of 90 minutes 500 cc. of blood were administered and 450 cc. removed.

*Results* The infant withstood the procedure well. The hemoglobin concentration of the blood after the transfusion was 16 grams per cent. However, by the seventh day it had fallen to 13.5 grams per cent and the patient became severely jaundiced. On the eighth day of life the serum bilirubin concentration was 16 mg. per cent, but this fell to normal by the fifteenth day. During this time there was a gradual

37th week	0	6	44

decline in the hemoglobin concentration of the blood to 8.5 grams per cent and the baby was given another transfusion this time of Orh blood on the fifteenth day, following which the hemoglobin concentration rose to 15.5 grams. Except for a bout of diarrhea that developed at the age of one month the baby has since done well.

This case is instructive in illustrating the method of determining genotypes. The father belonged to phenotype  $Rh_1rh$  so that on this basis he belonged to one of the three genotypes,  $R^1r$ ,  $R^0r^1$ , or  $R^1R^0$  of which the first is the most common and therefore the most likely. For this reason, type  $Rh_1rh$  individuals are usually presumed to be heterozygous.<sup>8</sup> However, when it was found that the first two children belonged to type  $Rh_0$ , this excluded genotype  $R^1r$  leaving genotypes  $R^1R^0$  and  $R^0r^1$  as the remaining possibilities. When finally the new baby proved to be  $Rh_1$  it was apparent that the genotype of the father is  $R^1R^0$  so that he is homozygous for the  $Rh_1$  factor even though he belongs to phenotype  $Rh_1rh$ . Obviously, every future child of this couple will be erythroblastotic.

This case is unusual in that the baby developed a hemolytic anemia despite the exchange transfusion and required a supplementary transfusion before the blood count was stabilized. It is possible that this was due to sensitization with the A factor, and this interpretation is supported by the excellent response to subsequent transfusion of group O, type rh blood.

Despite the additional complication of diarrhea, the child did well, is one year old at the time of this writing and is normal.

**CASE 6**—This baby was referred to us at the age of 1 day for treatment by exchange transfusion. Studies done elsewhere had shown the mother to be Rh negative and the father to be Rh positive. Blocking antibodies were detected in the mother's serum during her pregnancy and were said to be 4 plus. The baby was the result of the second pregnancy. The first baby was jaundiced at birth but the jaundice cleared after several days without treatment and this child is well. One and one half years before the onset of the first pregnancy the mother had received a transfusion of blood from her husband.

**Findings:** On examination the infant was pale and jaundiced. The hemoglobin concentration of the blood was 11.4 grams. The spleen and liver were moderately enlarged and the child's general condition was good.

Grouping and Rh-Hr tests done on the father, mother and the infant are shown in table 5.

No antibodies could be detected by the saline agglutination test in the mother's serum but the blocking test<sup>17</sup> was positive to a titer of 1½ units. By the albumin plasma technic, univalent Rh antibodies

TABLE 5

Blood of	Group and subgroup	M N type	Rh-Hr type	
			Phenotype	Genotype
Father	O	N	Rh <sub>1</sub> Rh <sub>1</sub>	R <sup>1</sup> R <sup>1</sup> or R <sup>1</sup> r'
Mother	A <sub>1</sub>	M	rh	rr
Infant	O	MN	Rh <sub>1</sub> rh	R <sup>1</sup> r

were demonstrable in a titer of 40 units. Furthermore, the infant's cells were completely coated\* by univalent Rh<sub>0</sub> antibodies as shown by the fact that they behaved in the tests as though they belonged to type rh.<sup>18</sup> In addition, free univalent antibodies were demonstrated in the baby's serum in a titer of 3 units by the albumin plasma agglutination test.

**Prognosis:** This infant was already erythroblastotic when seen and in view of the complete coating of the erythrocytes by univalent antibodies was probably in imminent danger of developing serious intra-vascular clumping.

**Procedure:** Exchange transfusion was performed using the blood of a donor belonging to group O type rh. One half of the donor's plasma was removed and replaced with normal saline in order to reduce the conglutinin content of the infused blood. Five hundred and fifty cc. were administered into the saphenous vein and 500 cc. of blood were withdrawn from the radial artery. The baby was returned to the ward in excellent condition.

**Results:** The day following the procedure the hemoglobin concentration of the blood was 12 grams per cent and the infant's general condition was good. The icterus index which had been 60 units at the onset of the procedure, was now 64 units and differential agglutination tests showed that a replacement of about 85 per cent of the red cells had been accomplished.

Two days after the transfusion the baby began to show signs of irritability and his temperature rose to

\* The cells of all typical erythroblastotic babies are coated by univalent antibodies as can be demonstrated by suspending the cells in plasma or albumin plasma mixture or by the anti globulin technic. If in addition the baby's Rh positive cells are 'blocked' as shown by their failure to clump in good anti Rh<sub>0</sub> agglutinating serum they are considered to be completely coated.

101 F The urine was found to contain 10-25 white blood cells per high power field and culture was positive for staphylococcus aureus. The Chvostek, peroneal and Trousseau signs were positive and the serum calcium was found to be only 7.3 mg per cent. The child was treated with intravenous calcium gluconate, calcium by mouth and given penicillin and sulfa therapy. Within a few days the temperature fell to normal, the calcium concentration of the serum returned to normal levels and the urine cleared. When discharged at the end of eight days, the child's hemoglobin concentration of the blood was 10.6 grams and he was clinically well. At the age of 3 months the child weighed 15 pounds and the hemoglobin concentration was 12.2 grams per cent. There were no subsequent transfusions given, and the child developed normally.

CASE 7—The mother of this infant was first seen in the eleventh week of her fourth pregnancy. Her first and second pregnancies had ended at term, and both of these children are alive and well. Her third pregnancy resulted in the birth of a full term infant who seemed to be well at first but then became

jaundiced and was transfused eight hours after birth. This infant died on the third day of life. The clinical diagnosis made at that time was cerebral hemorrhage.

*Findings.* Grouping and Rh Hr tests done on the father, mother and both surviving daughters gave the results shown in table 6.

Antibody studies done on the mother's blood at intervals during her pregnancy gave the results shown in table 7.

*Prognosis.* An autopsy report on the infant that died is not available but from the clinical symptoms described it is evident that the death may have been due to erythroblastosis. This belief is strengthened by the finding of a moderately high antibody titer in the maternal serum early in the following pregnancy. Since the father was Rh positive and almost surely homozygous it was anticipated that the new baby would be Rh positive and also have moderately severe erythroblastosis.

*Procedure.* In order to limit the period of time over which the infant would be exposed to the action of the maternal antibodies, labor was induced two weeks before term. The infant, a girl, appeared to be normal. There was a faint yellow streak along the umbilical cord but the amniotic fluid was not yellow and the vernix was not discolored. Exchange transfusion was carried out immediately using 540 cc. of blood from an A<sub>1</sub>Nth donor for the infusion while 480 cc. of blood was withdrawn. Half of the plasma had been removed from the donor's blood and replaced with saline in order to reduce the conglutinin content of the infused blood. The baby withstood the procedure well.

**Results** The infant's course was entirely uneventful except for the appearance of moderate jaundice on the second day. This subsided rapidly. No hepatic or splenic enlargement was made out at any time. The infant's blood group was  $A_1MRh_{17}rb$ , and a positive reaction was obtained with the agglutination test for coating of the infant's red cells. Furthermore, free Rh antibodies of 4 units titer could be demonstrated in the baby's serum by the agglutination method. On the day following the transfusion the hemoglobin was 17.4 grams per cent and the red blood cell count 5.04 million per cu mm. Three normoblasts per 100 white blood cells were present on the smear. The child left the hospital on the fifth day of life in excellent condition. When seen again at the age of 4 months the child was alert and held its head up well.

**CASE 8**—This baby, a female, was first seen on the second day of life. No antenatal studies had been done on the mother during pregnancy. Her first child was born two years previously and was well. The mother had received no transfusions or blood injections at any time. At birth the infant appeared to be normal but on the second day of life rapidly became jaundiced. The hemoglobin concentration was found to be 11.7 grams per cent and the red blood count 2.9 million per cu mm. Seven nucleated red blood cells per 100 white blood cells were found on the smear.

**Findings** Grouping and Rh Hr tests done on the father, mother, and infant gave the results shown in table 8.

Weak agglutinins were demonstrable in a titer of 8 units in the mother's serum but by the albumin plasma agglutination technique univalent antibodies were demonstrable in a titer of 40 units.

TABLE 8

Blood of	Group and subgroup	M N type	Rh Hr type	
			Phenotype	Genotype
Father	A	M	Rb <sub>1</sub> rh	R <sup>1</sup> R <sup>0</sup> or R <sup>0</sup> r'
Mother	A <sub>1</sub>	MN	rb	rr
Patient	O	M	Rb <sub>0</sub>	R <sup>0</sup> r

**Prognosis** Inasmuch as the above titers were determined only one day postpartum, these titers were presumably the same as those existing just before delivery, so that moderately severe sensitization was present and the prognosis was fair if intravascular clumping had not already occurred, and provided that an exchange transfusion were done immediately. With simple transfusion therapy the likelihood of recovery seemed to be remote.

**Procedure** Exchange transfusion was performed when the baby was 36 hours old. Over a period of one hour 550 cc. of group O, type rh blood were injected and 475 cc. of blood removed.

**Results** The hemoglobin concentration of the blood was 15.9 grams per cent after the transfusion with a red blood count of 5.2 million per cu mm. There were 4 nucleated red blood cells per 100 white blood cells on the smear. The icterus index before the procedure was 70 units and after the procedure had been reduced to 50 units. Titration of free Rh antibodies by the albumin plasma agglutination method done on the infant's plasma showed a pretransfusion concentration of 1½ units and a post transfusion concentration of 1½ units.

The baby withstood the procedure very well and the jaundice had almost completely faded three days after treatment, at which time the baby was discharged from the hospital. When seen at the age of five weeks the hemoglobin concentration was 14.3 grams per cent and the red blood cell count was 5.05 million per cu mm. the baby was entirely well clinically.

The obstetrician was so impressed by the improvement of the baby by the transfusion that he sent her home with her mother on the fourth day postpartum without even consulting us. This spectacular result cannot be duplicated by any case seen in the days before exchange transfusion. Comparable cases in the past have

either showed progressive jaundice despite transfusion, with early death from kernicterus, or have recovered following a series of transfusions over a period of weeks or months, sometimes only to exhibit sequelae of liver and brain damage later on

**CASE 9**—When first seen, the mother of this patient was in the interval between her first and second pregnancy. Her first pregnancy, three months previously, had been terminated by cesarean section in the thirty fifth week because of central placenta previa. She received two transfusions at that time. The infant weighed 2½ pounds and lived for only twelve hours. Studies were requested to determine if isoimmunization had any bearing on the loss of the infant.

**Findings** Grouping and Rh Hr tests done on the husband and wife gave the results shown in table 9.

At the time that these studies were done tests for antibodies in the mother's serum showed an agglutinin titer of 2 units while the titer by the plasma conglutination test was also 2 units. It seemed much less likely that the sensitization had been caused by the pregnancy than by the two transfusions that the woman had received. Inasmuch as the husband was most probably heterozygous for the Rh factor there

37th week	6	10

was an even chance that any future pregnancy would produce either an Rh positive or an Rh negative infant. Furthermore, since sensitization was only mild there was a possibility that even if she had an Rh positive infant it would be only moderately or mildly affected and could be saved by the proper treatment.

The mother returned fourteen months later for further studies, in the twenty fourth week of her second pregnancy, and her serum was tested for antibodies at frequent intervals thereafter with the results shown in table 10.

**Prognosis** The absence of antibodies at the first examination followed by their appearance at the second examination, indicated that the mother was carrying an Rh positive fetus and that a moderately affected erythroblastic infant could be expected.

**Procedure** Because of the previous cesarean section it was felt that this child should also be delivered transabdominally. In order to limit the period of time that the infant would be in contact with the maternal antibodies cesarean section was done at thirty-seven weeks. Before proceeding with the exchange transfusion however the baby's blood was grouped and Rh tested in order to be certain that we were not dealing with an Rh negative child. As expected from the antibody tests the baby was Rh positive (A<sub>1</sub>MRhrh).

Exchange transfusion was performed using blood from an A<sub>1</sub>MNrh donor. Over a period of ninety minutes, 550 cc. were given and 500 cc. removed. The baby bore the procedure well.

*Results* The hemoglobin concentration at birth was 17.4 grams per cent, and the red blood count 6 million per cu mm. There was only 1 normoblast per 100 white blood cells on the smear. The icterus index was 28 units. The hemoglobin concentration following the procedure was 13.1 grams per cent and the red blood count 4.8 million per cu mm. The albumin plasma conglutination test on the cord serum could detect no free Rh antibodies, but by the acacia method a titer of 48 units was obtained on the baby's serum.\*

On the day following the transfusion jaundice appeared and deepened perceptibly on the second day.† The icterus index at this time had risen to 72 units. The infant remained clinically well, however, and took its feedings without difficulty. The hemoglobin concentration remained unchanged. The spleen became slightly enlarged, but the liver was not palpable. By the eighth day the spleen was no longer palpable and the jaundice was fading rapidly. The patient was discharged from the hospital at the age of 2 weeks. At the age of 2 months the hemoglobin concentration had fallen to 8.4 grams, but reticulocytes were present on the blood smear and a differential agglutination test showed that as much as 90 per cent of the infant's blood was Rh positive, indicating that regeneration of blood was proceeding at a satisfactory rate, and that further transfusion was not necessary.

When seen again at the age of 3 months, the child was perfectly well and developing normally both mentally and physically.

### Fatal Cases

CASE 101.—The mother of this patient was first seen in the second trimester of her fifth pregnancy. Her first two pregnancies had yielded normal infants who are well today. Her third pregnancy resulted in the birth of a stillborn fetus at term. Life had been felt until three days before delivery. Her fourth pregnancy terminated spontaneously at 36 weeks with the birth of a stillborn infant which had apparently been dead *in utero* for about two weeks.

*Findings* Grouping and Rh Hr tests done on the entire family gave the results shown in table II.

Antibody tests done on the mother's plasma during the second trimester were positive to a titer of 4 units both in saline and plasma media, indicating a mild sensitization to the Rh factor with antibodies predominately of the bivalent type. At the beginning of the third trimester, however, the antibody titer had risen to 12 units by the agglutination method and to 25 units by the plasma conglutination technique.

*Prognosis* Since the husband was presumably homozygous for the Rh factor there was little doubt that the stillborn infants from the third and fourth pregnancies had died of erythroblastosis. Furthermore, in view of the significant rise in antibody titer, the expected infant would undoubtedly be Rh positive and stillborn if the pregnancy were allowed to go to term.

*Procedure* A male infant weighing 5 lbs., 6 oz. was delivered by cesarean section six weeks before term. At birth the cord was seen to be bile stained and the infant was pale and had a weak cry. Blood was taken

\* That this was not an artefact was proved by demonstrating that it was possible to distinguish Rh positive and Rh negative bloods by the acacia conglutination method using the infant's serum diluted 1 to 8 with saline solution as the testing serum.

† Subsequent experience has shown that it is not uncommon for jaundice to increase for a day or two after the exchange transfusion before subsiding. This may be due to liver damage sustained before the institution of treatment.

for subsequent examination, but the exchange transfusion was carried out without delay. A total of 420 cc of blood was withdrawn and 500 cc injected. The baby withstood the procedure well. Subsequent tests showed that at birth, the hemoglobin concentration was 11.7 grams per 100 cc, the red blood cell count 2.62 million per cu mm with 18 nucleated red blood cells per 100 white cells on the smear. The total white blood count was 23,200 per cu mm. The icterus index at birth was 70 units. As expected the baby was Rh positive, the complete classification being OMNRh<sub>1</sub>rh<sup>+</sup>.

**Results.** Following the transfusion the hemoglobin concentration was 19.8 grams per cent, and differential agglutination showed that an exchange of about 90 per cent had been accomplished. The icterus deepened on the second day of life although the baby seemed to be clinically well. There was no hepatomegaly or splenomegaly. On the third day of life the baby became intensely jaundiced. The icterus index had risen to 110 units and the infant became lethargic and refused its feedings. In the latter part of the day, brown edema of both lower extremities became evident. The hemoglobin concentration had now fallen to 14.7 grams per cent. The subsequent course was downhill. The temperature fell to subnormal levels, the baby refused feedings and became dehydrated. Despite intravenous fluids he failed to improve. On the fifth day of life the temperature rose to 103.5 F and death ensued.

**Autopsy report.** Kernicterus, hepatosplenomegaly, necrosis of Hassell's corpuscles, hemorrhage into lungs, large areas of necrosis in the liver, islands of hematopoiesis in the liver, spleen and adrenals.

As is usual in many cases of erythroblastosis, the condition of this infant appeared to be excellent at the time of birth and immediately thereafter. We expected, therefore, that if the progress of the disease could be arrested by exchange transfusion this infant would survive. The death of this baby led us, in subsequent cases, to remove half of the plasma from donor's blood and replace it with saline, thus reducing the conglutinin content of the infused material and favoring hemolysis instead of clumping. The promise of this procedure was not fulfilled and it has therefore been abandoned. We have now further changed our procedure by using 1,000 cc of blood instead of 500 cc in the more severe cases, and our limited experience up to the present time indicates that many more of these severe cases can be saved with this modification, which ensures an exchange of 98 per cent of the infant's blood instead of only 87 per cent, thus obviating any possibility of further clumping or hemolysis.<sup>1, 2</sup> Even this modification is not universally successful as will be seen from the case presented below.

**CASE 106.**—This infant was the sibling of case 102. The mother became pregnant again about six months after delivering the baby just described and her blood was carefully followed with repeated antibody titrations prior to delivery. The results of these tests are shown in table 12.

**Prognosis.** In view of the rising titer of antibodies and the history of the loss of three previous infants from erythroblastosis, the prognosis for the expected child appeared to be hopeless if the pregnancy were permitted to go to term; in fact, the fetus would be expected to die *in utero* before the end of the eighth month. The only chance for survival was to deliver the baby while it was still alive and perform a massive exchange transfusion immediately after birth. Even at this time the manifestations were apt to be severe, so that the prognosis was grave.

**Procedure.** Cesarean section was performed six weeks before term. On exposing the uterus a small herniation the size of a walnut was found in the anterior uterine wall. This was covered only with peritoneum and was filled with blood.† On palpation, the hernia ruptured and bled profusely and the

\* Actually, the cells failed to clump in anti Rh<sub>0</sub> serum, due to coating of the red cells by blocking antibodies.

† In view of this defect in the uterine wall, the patient might have died of a ruptured uterus had she been permitted to go into labor. The development of the defect with the resulting detachment of the underlying placenta may account for the rise in the maternal antibody titer, as such a defect would permit fetal blood to enter the maternal circulation and stimulate the production of additional antibodies.

operation was completed rapidly by extending the incision through the herniation. The infant on delivery, weighed 5 pounds and 1 ounce and exhibited extreme pallor. Respirations were shallow and infrequent and a moderately large amount of blood and mucus had to be aspirated from the pharynx and trachea. Before the cesarean operation two donors belonging to group O type rh had been bled of 500 cc each and this blood was ready for immediate transfusion. Within a few minutes the baby was given 100 cc of blood and showed marked improvement in its general condition. It did, however, become cyanotic when oxygen was withheld. Exchange transfusion was then completed with the administration of a total of 1,000 cc of blood and the removal of 950 cc. Throughout the procedure the baby required frequent aspiration and continuous oxygen inhalation. Fifteen cc of 10 per cent calcium gluconate were given in divided doses of 5 cc each during the procedure which took a total of two hours. On being returned to her incubator the infant appeared to be quite well.

**Results:** During the next twenty four hours the baby was fairly active. She had one period of apnea which responded to artificial respiration and she also exhibited a few tremors which responded to the intravenous administration of calcium gluconate. On the morning following the procedure when the baby was about 24 hours old she suddenly expired.

Laboratory studies done on the cord blood obtained at birth showed hemoglobin concentration, 5.8 grams per cent, red blood cells, 1.5 million per cu mm, white blood cells 4,800 per cu mm, polys 33, myelocytes, 2, lymphocytes, 61, monocytes 3, eosinophiles 1. There were 45 nucleated red blood cells

34 weeks (4 days before Cesarean operation)	32	26

per 100 white blood cells on the smear. The icterus index was 52 units. The albumin plasma conglutination test for coating of the infant's cells was positive. The baby's group was OMRh<sup>+</sup>.

After the transfusion the hemoglobin concentration of the infant's blood was 13.2 grams per 100 cc and there were 124 nucleated red blood cells per 100 white blood cells.

At autopsy the liver was found to be greatly enlarged with large areas of necrosis, so that there is little doubt that this infant died as the result of damage caused by the maternal antibodies while the fetus was still *in utero*. It may still be possible, we feel, to save some severely affected infants with less involvement of the liver but who would otherwise die, if the hemoglobin concentration is maintained at normal levels by allowing a larger margin of infused blood over that removed. In this case, a margin of only 50 cc was allowed and the hemoglobin concentration was only 13.2 grams per cent following the transfusion. We have subsequently found that when a 100 cc margin instead of 50 cc is allowed in an exchange transfusion of 1,000 cc one is more likely to attain a normal hemoglobin concentration of the newborn, namely, about 16 grams. When the patient is extremely anemic as this infant was, a margin as great as 150 cc is desirable in order to correct the reduction of blood volume usually present in such cases.<sup>15</sup>

CASE 11. This infant was born in a city 250 miles away and was not under our complete management at any time. The only data available to us antenatally was that the mother was Rh negative and we were told that her serum contained Rh agglutinins in a titer of 64 units shortly before birth. The baby became extremely jaundiced by the fourth day of life at this time it was lethargic and cyanotic, and had to be placed in an oxygen tent. Exchange transfusion was then performed by us at the request of the attending physician, as a measure of last resort. The infant seemed to be improved immediately following the procedure, but died about five hours following its completion.

CASE 12. The mother of this patient was first seen by us two years after her fourth pregnancy. Her obstetrical history at that time was as follows. Her first pregnancy terminated with the birth of a male infant who was cyanotic, required resuscitation and lived for only two days. Her second pregnancy yielded a normal male infant who is alive and well. Following this she gave birth to a full term male infant who developed jaundice and lived for only twenty-five hours. Her fourth pregnancy yielded a stillbirth two weeks before term.

*Findings.* Grouping and Rh-Hr tests done on the father, mother and living child gave the results shown in table 13.

Test for Rh antibodies on the mother's serum gave the following results. Agglutination test—negative, Blocking test—positive 2 units. Plasma conglutination test—positive 30 units. These results confirmed the diagnosis of erythroblastosis as the cause of the death of the third infant, and as the cause of the stillbirth which occurred in the fourth pregnancy. In view of the presence of a high titer of univalent antibodies and the fact that the husband belonged to type Rh<sub>1</sub>Rh<sub>2</sub>, every child of this couple would almost surely be Rh positive and stillborn, so the parents were advised against further pregnancies.

The mother was seen again in the sixth week of her fifth pregnancy and from that point on repeated titrations were done until delivery. The results of these studies are shown in table 14. At the time that the last antibody test was done examination by the attending obstetrician revealed that hydramnios had developed.

*Prognosis.* In view of the high titer of univalent antibodies and the development of hydramnios indicating fetal pathology, there was little hope of saving this baby unless delivery was carried out immediately and exchange transfusion performed. Intrauterine death seemed to be imminent if the pregnancy were to be allowed to continue for even a few more days.

*Procedure.* Delivery by cesarean section was carried out at thirty six weeks. The infant was pale and

icteric at birth and weighed 5 pounds 8 ounces. Blood was taken for tests to be carried out subsequently and immediate exchange transfusion was performed, using fresh citrated blood from an A, rh donor. One half of the plasma was removed from the donor's blood and replaced by an equal volume of normal saline. Over a period of 90 minutes 440 cc. of blood were injected and 380 cc. removed. The baby withstood the procedure well but was having respiratory difficulty when it was sent to the nursery.

**Results.** The hemoglobin concentration was 9.0 grams per cent at birth with a red blood cell count of 2.2 million per cu. mm. The infant belonged to group O type M type Rh<sub>1</sub>rh. The coagulation test for coating of the infant's erythrocytes were positive and free univalent antibodies could also be detected in the baby's serum.

Following the transfusion the hemoglobin concentration of the blood was 9.4 grams with a red blood cell count of 3.9 million per cu. mm. There were 164 nucleated red blood cells per 100 white blood cells on the smear. For two days the jaundice deepened gradually and the baby became lethargic and began to take its feedings poorly. On the third day of life the hemoglobin concentration had risen to 10.6 grams per cent with a red blood cell count of 4.7 million and there was still 200 nucleated red blood cells per 100 white cells on the smear. The jaundice deepened, the infant began to ooze blood from the mouth, developed respiratory distress and expired.

Through mischance this baby was left with a hemoglobin concentration of only 9.4 grams per cent at the end of the procedure, and this, we believe, contributed to its death. While in other cases following the exchange transfusion the erythroblasts quickly disappeared from the baby's blood stream, in this case they increased in number, possibly due in part to the anemia. A sample of blood obtained post-mortem showed twice as many Rh-positive cells as the immediate post-transfusion sample, while in our successful cases differential agglutination tests show no Rh-positive blood cells on the third day. The increase in the proportion of the Rh-positive cells nullified the procedure, and prevented recovery of the baby.

**CASE 13.** The mother of this patient was first seen by us in the twenty-fourth week of her second pregnancy because she had been found to be Rh negative in routine prenatal tests done elsewhere. Her first pregnancy had terminated spontaneously at term four years before with the birth of a male infant who is now well. This child had no anemia or jaundice. There was no history of the mother having had a transfusion or injection of blood or plasma.

**Findings.** Grouping and Rh Hr tests done on the father, mother and son gave the results shown in table 15.

Tests for antibodies were done on the mother's serum at intervals during the remainder of her pregnancy with the results shown in table 16.

**Prognosis.** These results indicated that the mother had become strongly sensitized to the Rh factor with antibodies predominantly of the bivalent type, and that the infant would probably have severe erythroblastosis.

**Procedure.** Plans were made to deliver the baby prematurely and perform an immediate exchange transfusion. However, the mother went into labor spontaneously in the thirty-fifth week of pregnancy and delivered a female infant who weighed 5 pounds, 15 ounces, was pale, but not icteric and could be resuscitated only with great difficulty. Immediate exchange transfusion was carried out with the administration of 560 cc. of blood from a donor who belonged to group O type rh and the removal of 460 cc. of blood. The baby withstood the procedure well.

**Results.** Examination of the infant's blood taken immediately after birth showed the hemoglobin concentration had been only 4.3 grams per cent. The albumin plasma coagulation test for coating of the infant's cells was positive and the serum of the cord blood showed the presence of free Rh antibodies in a titer of 3 units by the albumin plasma technique. On the day following the transfusion the hemoglobin concentration of the blood was 13.5 grams, the red blood cell count 4.2 million per cu. mm. and the white cell count 20,650. There were 220 nucleated red blood cells on the smear. The infant on that day began to show slight jaundice, there was some edema of the extremities and respirations were grunting and rapid. Five râles were audible throughout the entire chest, and cyanosis developed when oxygen

therapy was discontinued for feedings. Forty-eight hours after the procedure the picture became alarming. The liver and the spleen were both firm and readily palpable about three centimeters below the costal margins, petechiae were present over the shoulders and extremities and marked jaundice had developed. The hemoglobin concentration was now 13 grams per cent and there were 250 nucleated red blood cells per 100 white blood cells on the smear. The infant was given a transfusion of 60 cc. of group O, type rh blood and seemed to show some improvement for several hours. On the third day of life, however, dyspnea became more severe, the jaundice appeared to be deeper and the child refused all of its feedings. Blood taken several hours before death showed a serum bilirubin of 12.2 mg. per cent, and a prothrombin time of over three minutes as compared with the control of twelve seconds.

The findings at autopsy were kernicterus, cholemic nephrosis and pulmonary congestion, edema and atelectasis with foci of hematopoiesis in the liver and spleen.

CASE 14 This case is reported in detail elsewhere.<sup>10</sup>

CASE 15—This infant was first seen by us a few hours after birth because of severe anemia. Delivery had been spontaneous and at term. Pallor was noted immediately, and the amniotic fluid was seen to be

yellow. The infant's hemoglobin at birth was 5.8 grams per cent with a red blood cell count of 1.25 million. This was the mother's first pregnancy. She had no history of having had any abortions or miscarriages. Ten years before she had had poliomyelitis and was given a blood transfusion at that time.

Findings: Grouping and Rh-Hr tests as subsequently determined on the mother, father and the newborn infant gave results shown in table 17.

Tests done on the mother's serum for the presence of antibodies showed that the blocking test was positive in a titer of 4 units while the albumin plasma conglutination technique gave a titer of 100 units. Coombs' antiglobulin test for coating of the baby's erythrocytes was positive and the infant's plasma contained free polyvalent antibodies in a titer of 40 units by the albumin-plasma conglutination technique. The icterus index of the baby's serum was 40 units.

Prognosis: Although the above information was not available to us at the time that the baby was first seen, it was clear that the child was severely affected with erythroblastosis and the prognosis was very poor.

Procedure: Exchange transfusion was performed about five hours after birth. Because of the need for haste, group O type rh bank blood was used. One third of the plasma was removed and replaced with an equal quantity of normal saline. The infant received 500 cc. of blood while 450 cc. were removed.

Results: There was an immediate improvement in the baby's condition following transfusion but on

the following day, the patient again looked pale and was given another 75 cc of blood from a donor who belonged to group O, type rh. On the third day following the exchange transfusion jaundice developed and deepened rapidly. The hemoglobin concentration had now fallen to 10.1 grams per cent from the level of 12.3 grams that was present immediately following the exchange transfusion, and a second supplementary transfusion of 75 cc of fresh blood was given. Progress was not satisfactory, however. The icterus deepened, the liver and spleen became enlarged and the baby became lethargic and had intermittent periods of cyanosis. At the end of one week the temperature rose to 103 F and the anterior fontanelle was found to be bulging. Spinal tap revealed a canary yellow fluid that contained 7 white blood cells and 5 red blood cells per cu mm. The Pandy reaction was 4 plus and the qualitative sugar reaction on the spinal fluid was 3 plus. The blood culture was positive for staphylococcus aureus. Despite penicillin therapy, a large abscess which yielded 8 cc of purulent fluid on incision and drainage appeared over the upper thoracic vertebrae. Culture of this material was also positive for staphylococcus aureus. The baby developed diarrhea and scattered indurated areas over the body on the twenty ninth day of life and expired the following day.

Autopsy revealed bacteremia, pyohydrocephalus, abscesses in the thyroid, heart, kidney and the brain, kernicterus cirrhosis of the liver, septal thrombophlebitis of the pulmonary veins, and focal pneumonia.

### Cases of Moderate Severity

CASE 16—This case has been reported in detail elsewhere.<sup>5</sup>

CASE 17—The mother of this patient was first seen by us in the first trimester of her third pregnancy. She had delivered a normal boy seven years previously who is living and well. Her second child, a boy, was born three years ago. He was normal at birth, but on the second day of life was seen to be jaundiced. The hemoglobin concentration of his blood was 7.3 grams per 100 cc and the red count was 2.3 million per cu mm. He was found to be Rh positive while the mother was Rh negative. Over a period of twelve days he received three transfusions of 75 cc each of group A, Rh negative blood without showing any appreciable rise in hemoglobin concentration or red blood count. On the fifteenth day of life, however, he was given 105 cc of washed mother's red cells in two portions and his hemoglobin concentration rose to 12 grams per cent. From this point onward his recovery was uneventful. At the time when his jaundice was at its peak the van den Bergh reaction showed a concentration of 46.7 mg of bilirubin in his blood.

*Findings.* Grouping and Rh-Hr tests done on the family gave the results in table 18.

At the time of the first test for Rh antibodies in the mother's serum no agglutinins were demonstrable, but univalent antibodies were shown to be present in a titer of 16 units by the plasma coagulation technique. Anti A and anti B titrations on the mother's plasma by both the agglutination and coagulation techniques were within normal limits. By the middle of the third trimester of pregnancy, however, Rh agglutinins could be demonstrated to a titer of 1½ units, while the coagulation titer had fallen to 3 units. A slight rise of both anti A and anti B titers above the normal was found at this time.

*Prognosis.* Since the anti Rh titer had fallen it could be confidently predicted that a viable infant would be obtained, even though the infant was almost certain to be Rh positive and therefore erythroblastotic. If the baby belonged to group A, the presence of mild sensitization to the A agglutino-gen might further complicate the picture, but probably not to a serious degree.

*Procedure.* The baby was delivered at term and was observed for twelve hours. Studies done during this time showed that the hemoglobin concentration of the blood was 14.5 grams per 100 cc. The red blood

count was 4.7 million cells per cu. mm. and the white blood count 26,200 per cu. mm. There were 20 nucleated red blood cells per 100 white blood cells and the icterus index of the cord serum was 12 units. The infant proved to belong to group  $A_2MNRh_1rh$ . After twelve hours the icterus index had risen to 24 units and the baby began to show slight clinical jaundice.

Exchange transfusion was carried out using a donor that belonged to group  $A_1MNRh$ . To reduce the concentration of the conglutinin in the infusion material, half of the plasma was removed from this blood and replaced with saline. Ten cc. of Wittebsky group substances were then added to neutralize the alpha antibodies present in the infant's body and derived from the mother. The usual procedure was then carried out, 500 cc. of blood being injected and 460 cc. simultaneously removed.

**Results.** The hemoglobin concentration was 13.5 grams per 100 cc. on the day following the transfusion. By the sixth day it fell to 8.8 grams per cent and another transfusion of 70 cc. of blood this time from an  $A_2rh$  donor was given. The hemoglobin rose to 12.7 grams per cent but over the next five days fell again to 8.7 grams. Following a final transfusion of 60 cc. of  $A_2rh$  blood the hemoglobin concentration became stabilized and the baby was discharged from the hospital. The van den Bergh reaction, which was indirect, showed a concentration of 5.7 mg. of bilirubin per 100 cc. at 3 days of age and fell steadily to normal during the hospital stay of three weeks. At the age of 2 months the hemoglobin concentration was 10.7 grams per cent and the baby was well. Some splenic enlargement was noted at that time but

TABLE 18

Blood of	Group and subgroup	M N type	Rh Hr type	
			Phenotype	Genotype
Father	A	MN	Rh <sub>1</sub> Rh	$R^1R^2$ or $r^1R^1$

1st son	O	MN	Rh <sub>2</sub>	$R^2r$
2nd son	A	N	Rh	$R^2r$

was no longer demonstrable 6 months later. At the age of one year the child was perfectly normal in every respect. He stood and was beginning to take a few steps. Language development was normal for that age.

This case is unusual in that the patient required two supplementary simple transfusions after the exchange transfusion, while in typical cases the exchange transfusion alone is sufficient to bring about a cure. This may be ascribed to the fact that the mother was sensitized to the agglutinin A as well as Rh, and especially to the use of blood of subgroup  $A_1$  for the exchange transfusion instead of blood of subgroup  $A_2$  or group O. The titer of alpha antibodies in the maternal serum was only slightly elevated, so that ordinarily one would expect the alpha antibodies passing into the fetal circulation to be completely neutralized by the A substance in its blood and tissues, leaving no free alpha antibody to affect the transfused group A blood cells. In this case, however, the baby belonged to subgroup  $A_2$ , so its tissues and blood were capable of neutralizing only the common alpha antibody, leaving alpha<sub>1</sub> antibody free to lyse the transfused  $A_1$  cells. While this prolonged the baby's illness, recovery readily resulted after two simple, supplementary transfusions of blood of subgroup  $A_2$ .

**CASE 18.**—No antenatal tests had been done in this case. The infant was referred to us when she was 9 hours old because of jaundice and anemia. She was the product of the second pregnancy. The first pregnancy was uncomplicated and resulted in the birth of a normal child who is living and well today. The

patient was born at term and was definitely icteric at birth. At the age of 5 hours the hemoglobin concentration was only 8.1 grams per cent and there were 15 normoblasts per high power field on the blood smear. The baby was given 80 cc of group O type rh blood before she was referred to us.

*Findings.* Grouping and Rh Hr tests on the family gave the results shown in table 19.

Antibody tests done on the mother's serum showed that a mixture of both bivalent and univalent antibodies were present. The agglutination test showed a titer of Rh antibodies of 12 units while the titer by the albumin plasma conglutination technic was 28 units. The serum of the infant was shown to contain free univalent Rh antibodies by the albumin plasma conglutination test which was positive to a dilution of 1:2.

*Prognosis.* In view of the significant antibody titer and deepening jaundice (icterus index 22.0 units) this was a severely affected infant who required immediate and vigorous treatment.

*Procedure.* Exchange transfusion was carried out twenty-four hours after birth using bank blood from an O, rh donor from which half of the plasma had been removed and replaced by saline. The baby was given 560 cc of this blood while 510 cc were removed.

*Results.* On the day following the transfusion the baby seemed very much improved although the hemoglobin concentration of the blood was only 11.7 grams per cent. At eighteen hours after the procedure the baby again became deeply jaundiced and edema of the extremities, particularly the legs developed. The spleen and liver were now enlarged and examination of the blood smear revealed that there were 270 nucleated blood cells per 100 white blood cells. At the same time the hemoglobin concen-

tration had fallen to 9.0 grams per cent. This evidence of continued blood destruction was interpreted as being due to the fact that bank blood had been used for the exchange and a further small transfusion of 40 cc of fresh blood from an O, rh donor was given. The jaundice began to fade on the following day and by the next week had faded completely. The hemoglobin concentration which had risen to 12.7 grams per 100 cc following the supplementary transfusion was maintained and the baby was discharged from the hospital at the age of two weeks. No further transfusions were necessary. When the baby was last seen at the age of 8 months she was sitting alone and appeared to be normal in every respect.

This is one of the few cases in which a supplementary simple transfusion was necessary after the exchange transfusions were done. This we ascribe to the use of bank blood of uncertain state of preservation. We were compelled to use bank blood in this case because no compatible donor was available, and the baby's critical condition made it imperative to avoid any delay in starting the exchange transfusion. The case demonstrates that for exchange transfusion fresh citrated blood, if available, should be used instead of bank blood because the more satisfactory results with fresh blood more than compensate for its greater cost and inconvenience.

*CASE 19.*—The mother of this infant was first seen by us in the thirty-first week of her fifth pregnancy. Her first pregnancy four years previously resulted in the birth of a son who is living and well. Her second pregnancy terminated with the birth of a girl who is also normal. Her third baby, a girl, was well until

the fourth day of life when she became jaundiced and anemic. She received four transfusions of Rh negative blood over a period of two weeks and made a complete recovery. The birth of this baby was followed by a miscarriage at two months. There was no history of the mother ever having received a blood or plasma transfusion or blood injection.

*Findings* Grouping and Rh Hr tests done on the father, mother and all the living children gave the results shown in table 20.

Tests for Rh antibodies on the mother's serum showed that while the agglutination test was negative, the titer of univalent antibodies was 4 units as determined by the albumin plasma conglutination test.

*Prognosis* Since the father was almost surely homozygous for the Rh<sub>0</sub> factor the new baby would be expected to be Rh positive and therefore erythroblastotic, though not severely affected in view of the rather low Rh antibody titer of the maternal serum.

*Procedure* It was planned to deliver the infant at term and do an exchange transfusion immediately after birth. However, the mother went into labor spontaneously six weeks before term and delivered a 5 pound premature infant that seemed to be normal. Exchange transfusion was performed using 380 cc. of group O, type rh bank blood for the infusion and removing 300 cc. of blood from the baby. In this particular case the blood vessels were found to be uncommonly small and difficulty was encountered with the bleeding so that we actually were obliged to fall short of the 500 cc. mark that we had established for ourselves as the minimal goal in doing an exchange transfusion.

TABLE 20

1st daughter	O	MN	Rh <sub>1</sub> rh	R <sup>1</sup> r
2nd daughter (erythroblastotic)	O	MN	Rh <sub>1</sub> rh	R <sup>1</sup> r

*Results* The baby did well from the clinical point of view, that is feedings were taken normally and the weight gain was satisfactory. The baby did not develop any jaundice. However the hemoglobin concentration which was 16 grams per cent at birth was only 13.4 grams per cent on the day following the transfusion. Over the next eleven days the hemoglobin concentration fell to 10.5 grams per cent and the infant was discharged. Four days later the hemoglobin concentration of the blood had fallen to 8.0 grams and the patient was transfused with 55 cc. of group O, type rh bank blood. Two days later the transfusion was repeated and the hemoglobin concentration from that point onward was maintained at over 11 grams per cent. The child's subsequent course has been uneventful, though there is some slight doubt in the mind of the mother that he is as bright as his siblings.

*Case 20*—This one day old female infant was referred to us because of jaundice and anemia of six hours duration. She was the second child. The first a girl was 3½ years of age and was well. The mother had never been transfused and had never had any stillbirths or miscarriages.

*Findings* When first seen the infant was deeply jaundiced and had numerous petechiae on the forehead. The liver and spleen were not enlarged. The hemoglobin concentration of the blood was 12.3 grams per cent and red blood count was 3.4 million per cu. mm. The icterus index was 112 units.

Grouping and Rh Hr tests done on the mother, father and the patient gave the results shown in table 21.

Antibody tests done on the mother's serum were positive to 1½ units by the agglutination technic, and also by the plasma conglutination and albumin plasma techniques. Conglutination tests for coating of the baby's erythrocytes were negative and no free Rh antibody was demonstrable in the infant's serum.

*Progress* If one could depend entirely upon the maternal antibody titer as a criterion, this could be regarded as a case with only mild sensitization and therefore with a good prognosis. However the severe clinical condition of the infant, with deep jaundice and hemorrhagic phenomena called for more vigorous treatment than simple transfusion. We felt that with exchange transfusion the prognosis would be good and also that the need for repeated transfusions would be obviated.

*Procedure* Group O type rh bank blood was used. One half of the plasma was removed and replaced with normal saline. The baby received 450 cc while 450 cc was removed over a period of about ninety minutes. The baby withstood the procedure well.

*Results* On the following day the hemoglobin concentration of the blood was 13 grams per cent and the red blood cell count was 4.25 million per cu mm. There were 3 normoblasts per 100 white blood cells on the smear. The jaundice faded in three days and the child was discharged as well.

*CASE 21*—The mother of this patient was first seen in the thirty-sixth week of her third pregnancy. She had had a spontaneous miscarriage at 4½ months two years previously, and a spontaneous abortion at

Expectant mother	O	MN	rh	rr

2½ months about one year later. Three years ago she was operated upon for volvulus of the small bowel and had had 8 feet of ileum removed. She was given a blood transfusion postoperatively.

*Findings* Grouping and Rh Hr tests done on the prospective parents gave the results shown in table 22.

Test for Rh antibodies done on the mother's serum gave the results shown in table 23.

In view of the difference in the blood groups, titrations were also carried out for alpha and beta antibodies in the mother's serum. The results of these tests are shown in table 24.

*Prognosis* From the results of the Rh antibody tests, it was evident that the mother was definitely though weakly, sensitized to the Rh factor, and that it was likely that the expected infant would have mild erythroblastosis.

*Procedure.* In order to spare the infant prolonged contact with the antibodies it was planned to induce labor about two weeks before term and treat the infant with exchange transfusion but only if signs of erythroblastosis developed. The obstetrician elected to deliver the patient by cesarean section and this was carried out at the end of the thirty-eighth week of pregnancy.

The infant, a male, weighed 6 pounds and 1 ounce and appeared to be normal. There was no pallor, jaundice or hepatosplenomegaly. The hemoglobin concentration of the blood was 16.9 grams per cent and the red blood cell count was 4.14 million per cu mm. There was 8 normoblasts per white blood cells on the smear. The icterus index was 14 units and the baby's blood typed as AMNRh<sub>1</sub>rh.

Twenty-four hours after birth, slight jaundice was noted and blood studies showed that the hemoglobin concentration had now fallen to 13.5 grams per cent with a red blood cell count of 3.4 million per

cum mm Five normoblasts per 100 white blood cells were seen on the smear. No hepatic or splenic enlargement had developed. The serum bilirubin concentration was 9.5 mg/100 cc.

Exchange transfusion was performed with the administration of 520 cc. blood from an A<sub>3</sub>Nth donor, and the removal of 470 cc. The baby tolerated the procedure well.

**Results**—On the day following the procedure the hemoglobin concentration of the blood was 13 grams per cent and the red blood cell count 4.28 million per cu. mm. The jaundice was unchanged and the infant appeared well.

At this time there was an outbreak of diarrhea on the ward, and despite all precautions the patient developed loose watery stools and rapidly became dehydrated and acidotic. The CO<sub>2</sub> content of the blood fell to 22 volumes per cent and the patient was treated with starvation and parenteral fluids. Blood culture was negative and the stool culture was negative for pathogens. Feedings were resumed after twenty-four hours when the character of the stools returned to normal. Two days after the onset of diarrhea the hemoglobin concentration of the blood had fallen to 11 grams per cent and the red blood cell count to 3.9 million per cu. mm. The patient was transfused twice with 60 cc. blood from group O type Rh donors, and after the diarrhea was completely controlled was discharged 17 days after admission.

When seen at the age of 2 months he was well. He weighed 10 pounds and was not jaundiced.

### Mild Cases

**CASE 22**—The mother of this infant was first seen in the thirty-fifth week of her third pregnancy. Her first pregnancy had terminated prematurely with the birth of a normal female child. Her second infant, a female, was carried to term and was delivered normally. Both of these children are living and well. There was no history of the mother ever having received a transfusion or blood injection.

**Findings**—Grouping and Rh Hr tests done on the father, mother, and both children gave the results shown in table 25.

The results of the antibody titrations done on the mother's serum are given in table 26.

**Prognosis**—These findings indicated that the expected infant would almost surely be Rh positive and therefore erythroblastic, since the mother was sensitized to the Rh factor. However, since the Rh agglutinins in the maternal serum interfered with the determination of the titer of univalent antibodies, if any, the severity of the manifestations in the baby were not predictable.

**Procedure**—Labor was induced in the thirty-ninth week of pregnancy and the infant, a female, was immediately treated by exchange transfusion. Over a period of one hour 500 cc. of blood from an O Rh donor were injected and 480 cc. removed. The baby stood the procedure well.

**Results**—No clinical symptoms of erythroblastosis ever developed. The baby's hemoglobin concentration at birth was 17.4 grams per cent and the red blood cell count 4.3 million. There were no erythroblasts on the smear. Coating test on the baby's red blood cells (OMNRh<sub>2</sub>) was negative. On the day following

the transfusion the hemoglobin concentration was 15.5 grams. Mild icterus made its appearance on the second day of life but faded rapidly thereafter. The baby was discharged on the fourth day.

**CASE 23**—This was the mother's second pregnancy. Her first pregnancy was normal and went to term but labor was prolonged and the infant was delivered by high forceps. The child had no jaundice or anemia but its neonatal period was complicated by convulsions said to be due to cerebral hemorrhage attendant upon the traumatic delivery. Routine Rh tests done in the course of the second pregnancy revealed the mother to be Rh negative and sensitized to the Rh factor.

**Findings** Grouping and Rh Hr tests were done on the family, and the results are shown in table 27.

Antibody tests on the mother's serum done at thirty-six weeks were positive to a titer of 2 units by the agglutination technic and to a titer of 14 units by the albumin plasma conglutination technic.

TABLE 27

Blood of	Group and subgroup	M \ type	Rh Hr type	
			Phenotype	Genotype
Father	A <sub>1</sub>	MN	Rh <sub>1</sub> Rh <sub>1</sub>	$R^+R^+$ or $R^+r$
Mother	B	M	rh	rr
First child	O	M	Rh <sub>1</sub> rh	$R^+r$

**Prognosis** Since the husband was almost surely homozygous for the Rh<sub>0</sub> factor every child of this couple was bound to be Rh positive. In view of the moderately high titer of univalent antibodies in the mother's circulation an erythroblastotic infant with manifestations of only moderate severity was to be expected.

**Procedure** In order that the infant be spared unnecessarily prolonged exposure to the Rh antibodies delivery was carried out about 10 days before term. This was done by cesarean section because of the mother's contracted pelvis. Sterilization by ligation of the fallopian tubes was also done at this time. At birth the infant appeared to be perfectly normal clinically. The baby was grouped and was found to belong to group AB type Rh<sub>1</sub>rh and so was Rh positive as expected. Exchange transfusion was performed using blood from a group AB type rh donor. Over a period of forty minutes 560 cc. of blood were injected while 520 cc. were removed. The baby withstood the procedure very well. Studies done on the cord blood showed a hemoglobin concentration of 18 grams per 100 cc. with a red blood count of 5.75 million. No nucleated red cells were seen on the smear. However, the conglutination test for coating of infant's red cells by antibodies was positive.

*Results* The baby never developed either jaundice or anemia. It was discharged from the hospital on the 10th day and required no further transfusions. Differential agglutination studies showed that a 90 per cent replacement had been effectuated. At 3 weeks postpartum the titer of anti Rh agglutinins in the mother's serum had risen to 88 units while the antibody titer was shown to be 175 units by the albumin-plasma conglutination technic.

In most sensitized Rh-negative women, there is a rise in Rh antibody titer following the birth of the baby, probably due to leakage of infant's blood into the maternal circulation during labor. The case just described demonstrates that such a rise also occurs when delivery is accomplished by cesarean section, so that operative delivery does not prevent maternal sensitization. In view of the very high Rh antibody titer of the maternal serum after delivery and the fact that the husband belonged to type Rh<sub>1</sub>Rh<sub>1</sub>, it seems obvious that every future pregnancy would almost surely result in death of the fetus before it reached the stage of viability.

*CASE 14*—This infant was referred to us at the age of 2 days because of jaundice which had first been noticed when the baby was 17 hours old. The mother had had two previous pregnancies, and both children were alive and well. The first had been entirely normal during its neonatal period while the

TABLE 18

Mother	O	N	rh	rr
1st son	O	N	Rh <sub>1</sub> rh	R <sup>1</sup> r
2nd son	O	N	Rh <sub>1</sub> rh	R <sup>1</sup> r
Patient	A <sub>1</sub>	N	Rh <sub>1</sub> rh	R <sup>1</sup> r

second had developed jaundice on the second day of life and recovered after a brief illness. There was no history of the mother's ever having received any blood transfusions. Antenatal Rh testing had not been done.

The patient appeared to be normal at birth but jaundice was noted on the morning of the second day of life. The hemoglobin concentration was found to be 10.2 grams per cent and the icterus index 50 units.

*Findings* Forty-eight hours postpartum grouping and Rh Hr tests done on the family gave the results shown in table 18.

Antibody studies done on the mother's plasma showed that while no Rh antibodies could be demonstrated by the saline agglutination technic, weak univalent antibodies were present in a titer of 3 units as demonstrated by the albumin plasma method. Furthermore, univalent antibodies could be demonstrated in the infant's serum also in a titer of 2 units. Since there was a possibility of double sensitization (to A as well as to Rh) the mother's anti A and anti B titers were determined. By the agglutination method anti A was demonstrable in her serum in a titer of 40 units, and anti B in a titer of 12 units. By the plasma conglutination technic the titer of anti A was 60 units and anti B was 30 units.

*Prognosis* This then was a case of double though mild, sensitization to both the Rh factor and the A agglutino-gen. If untreated, the infant was bound to develop a mild but progressive anemia that would require several transfusions if treated in the usual manner. In view of the low antibody titers there was practically no danger of intravascular clumping.

*Procedure* In order to limit the number of transfusions required, an exchange transfusion was decided upon. Four hundred cc. of blood were withdrawn from the infant and simultaneously replaced by 500 cc. of blood from a group A type rh donor. Following the transfusion 10 cc. of Witte's A and B group

Half of the plasma was removed and replaced with saline. Five hundred and forty cc. were injected and 480 cc. withdrawn. The baby withstood the procedure well.

*Results:* At the end of the transfusion the icterus index was 45 units and on the day following had fallen to 30 units. The jaundice subsided rapidly and the baby was discharged from the hospital at the end of one week. At the age of 3 weeks the hemoglobin concentration of the baby's blood was 14.4 grams per cent. At the age of 3 months the child was doing well and seemed to be developing normally.

**CASE 26**—The mother of this infant was first seen by us in the thirty-seventh week of her second pregnancy. Her first pregnancy had terminated with the birth of a male infant who is well. Following the delivery the mother had a pulmonary embolus from which she did not recover for several months. She never had a blood or plasma transfusion. She had been found to be Rh negative by routine antenatal Rh testing but no antibodies had been found until a few days before she was referred to us.

*Findings:* Grouping and Rh Hr tests done on the father, mother, and son gave the results shown in table 31.

No agglutinins could be detected in the mother's serum and univalent antibodies of only one unit titer were found to be present by the albumin plasma technic.

*Prognosis:* Since the father was almost surely homozygous for the Rh<sub>0</sub> factor, the expected infant would be Rh positive. However, the low titer of antibodies in the mother's serum made it questionable that the infant would be affected by the disease. In fact, if erythroblastosis did develop at all, the manifestations would be expected to be very mild.

*Procedure:* Labor was induced at the end of the thirty-eighth week of pregnancy and a normal appearing baby girl weighing 6 pounds was delivered. The icterus index of the cord blood was 14 units and the hemoglobin concentration of the blood was 12.9 grams per cent with a red blood cell count of 4.33 million per cu. mm. There was one normoblast per 100 white blood cells on the smear. No jaundice or hepatosplenomegaly was noted. The albumin plasma conglutination test for coating of the infant's cells was negative though as predicted the baby was Rh positive (OMNRh<sub>1</sub>rh).

Twelve hours later the icterus index had risen to 28 units and it was decided that an exchange transfusion be performed. Blood was drawn from a donor who belonged to group O type rh and one half of the plasma removed and replaced with normal saline to reduce the conglutinin content. Over a period of one and one half hours 500 cc. of blood were injected and 450 cc. removed.

*Results:* Twenty-four hours after the transfusion the hemoglobin concentration of the blood was 16.1 grams per cent and the red blood cell count 5.4 million per cu. mm. The baby did not develop jaundice or anemia while in the hospital and was discharged with the mother on the fourth day. At the age of one week the hemoglobin concentration was 13.8 grams per cent and the red blood cell count 4.66 million. There was no jaundice present clinically and by differential agglutination the baby's blood typed as 100 per cent type rh. One week after delivery the titer of univalent antibodies in the mother's serum had risen to 10 units by the albumin plasma technic. No agglutinins were demonstrated. At the age of one month the hemoglobin concentration of the infant's blood had fallen to 8.4 grams and then rose spontaneously to 9.6 grams at the age of 2 months and to 12.9 grams per cent by the age of 3 months. Blood typing at this time showed that all the erythrocytes typed as OMNRh<sub>1</sub>rh, the baby's original type. The infant's subsequent course has been uneventful.

In retrospect, we consider this as a case that would have done well with the usual transfusion therapy or might even have recovered without any therapy at all. This case occurred early in our series and we were unduly impressed with the slight anemia and the rise in icterus index that occurred after delivery. Subsequently, we have seen 4 cases which had similar minimal titers of antibodies in the maternal serum. Of these, 2 developed mild clinical signs of erythroblastosis and recovered without therapy. The other 2 had no clinical signs of the disease at all.

**CASE 27**—The mother of this patient was first seen by us six months after her first pregnancy. This had terminated one month prematurely with a stillborn anencephalic male and was complicated by placenta previa. Following the delivery she received four transfusions of blood. She had chills and high fever.

following the first two of these but no reactions to the third or fourth. It is not known whether the blood she received was selected on the basis of Rh testing.

*Findings* Grouping and Rh Hr tests done on the woman and her husband gave the results shown in table 32.

Tests for antibodies done on the wife's serum showed that while no antibodies could be demonstrated by the saline agglutination technique, univalent antibodies of 4 units titer were shown to be present by the plasma agglutination method.

Six months later the antibody studies were repeated and this time no antibodies could be demonstrated by either the agglutination or the plasma agglutination techniques.

About six months after these tests were done she became pregnant again and the results of antibody tests done on her serum throughout her pregnancy are shown in table 33.

*Prognosis* Delivery was accomplished by cesarean section at the end of the thirty-seventh week of pregnancy. A blood count was done immediately after birth and showed that the hemoglobin concentration of the blood was 12.7 grams per cent and the red blood cell count was 3.8 million per cu. mm. There were 10 nucleated red blood cells per 100 white blood cells on the smear. In view of these findings an exchange transfusion was carried out with the administration of 500 cc. of group A type rh blood and the removal of 425 cc. of infant's blood.

*Results* The infant withstood the procedure well and on the following day the hemoglobin concentration was 17.1 grams per cent with a red blood cell count of 5.65 million. The baby never became jaundiced and was discharged on the eighth day. When seen at the age of 3 months the baby was well, had gained weight normally and appeared to be alert and active.

#### COMMENT

The case histories have been presented in considerable detail because it is only in relation to the severity of the individual case that the efficacy of the exchange

transfusion can be evaluated. Unfortunately, no comparable series of cases subjected to other types of treatment, such as simple transfusion therapy, is available for comparison. As we and others have shown elsewhere,<sup>1, 13</sup> the most reliable indication of the severity of the disease is provided by antenatal studies of the Rh antibodies in the maternal serum as well as through studies of the Rh antibodies in the infant's blood. This is demonstrated in table 34 which summarizes those cases that were studied antenatally.

Before discussing table 34 a few words are necessary concerning the relative roles of the bivalent and univalent antibodies in the pathogenesis of erythroblastosis. Whereas originally our tendency was to ascribe almost equal importance to the two kinds of antibodies,<sup>5</sup> the demonstration that the intact placenta allows blocking antibodies (glutinins or univalent antibodies) to pass across freely while holding back agglutinins (bivalent antibodies) has convinced us that the latter play only a subsidiary role in the disease.<sup>7</sup> In fact, the presence of agglutinins in the maternal serum may be entirely misleading, and in one case seen by us recently with an agglutinin titer of more than 100 units, the Rh positive infant subsequently born showed hardly any evidence of erythroblastosis. On the other hand, we have encountered no case with a significant titer of univalent antibodies in which an entirely normal Rh-positive fetus was subsequently born. Nonetheless, the presence of agglutinins is of some significance since it indicates that the mother has been sensitized so that her serum may well contain univalent antibodies in addition. Unfortunately, agglutinins react equally well in plasma and saline media, so that unless the univalent antibodies contained in the same serum are of significantly higher titer their presence would not be demonstrable with the methods available at the time that our cases were studied.\* Based on this concept one would expect that the severity of the manifestations in the erythroblastic baby should depend upon the titer of the univalent antibodies in the maternal serum as well as upon the length of time that they were present antenatally. To demonstrate this, the cases have been arranged according to the titer of maternal univalent antibodies at the last test before delivery. For the reasons just discussed these cases are divided into two groups, depending upon whether or not antibodies were also demonstrated by the saline agglutination method.

As shown in table 34, the severity of the manifestations parallels the titer of univalent antibodies in the maternal serum. The 5 infants† who died comprise the 2 with the highest titers in the first group and the 3 with the highest titers in the second group. In case 22 in the second group, the infant was but mildly affected, though the titer of the maternal antibodies was relatively high, in this case, the maternal serum most likely contained agglutinins with only weak accompanying univalent antibodies.

In table 35 are summarized those cases in which antenatal tests had not been

\* Utilizing the differences in behavior of univalent and bivalent antibodies such as the difference in resistance to heat, simple methods have been devised whereby univalent antibodies can be detected despite the presence of strong agglutinins.<sup>24</sup>

† This does not include case 11, because we had no access to the mother of this baby and so could not do our own antibody studies.

done, because the patients were not seen until the infants had developed obvious manifestations of erythroblastosis. Here again the correlation between the titer of maternal antibodies and the prognosis is apparent, since the only infant that died is the one whose mother had the highest antibody titer.

Observation of the infants treated by exchange transfusion immediately convinced us of the efficacy of the treatment so that we did not feel justified in withholding the treatment from any patient merely in order to set up a control series artificially. Since progress in the technics of demonstrating antibodies<sup>14</sup> has paralleled progress in therapy of the disease, even our own previous series do not constitute adequate controls because of incomplete serologic information. In

arranging the cases under the headings above, both the serologic findings and the severity of the clinical manifestations were taken into account, and it should be emphasized that in some of the severest cases (cases 2, 4, 7 and 8), the recovery after treatment was so rapid that it differed strikingly from anything experienced before this new type of treatment was instituted. It is true that 7 babies died despite treatment, but the clinical and serologic findings indicate that at least twice as many might have died if treated in the orthodox manner, namely, by multiple small transfusions of Rh-negative blood.

In the infants who responded to treatment the results were particularly gratifying for two reasons (1) The treatment besides being simple, was efficient, and only a few babies required supplementary treatment. In our opinion, it is simpler to do a single exchange transfusion than to do repeated simple transfusions, aside from the

greater efficacy of the former. In those cases that required supplementary transfusions, either bank blood had been used instead of fresh blood, or double sensitization (to A or B as well as Rh) was present. In some cases an intercurrent complication, unrelated to erythroblastosis, made further transfusions necessary. (2) All the infants who recovered developed normally, both physically and mentally, without any sequelae of liver or brain damage.

Some critics of the procedure have suggested that the infants who died succumbed to the effects of large amounts of citrate used as an anticoagulant in the transfused blood. Evidence<sup>19</sup> is available that the citrate is rapidly metabolized by the infants who survived and it is clear from the case histories that the infants that did not recover died in spite of, and not because of the treatment. The best disproof of the theory of citrate toxicity is our recent observations in which we were able to save infants by doubling the amount of blood used for the exchange transfusion despite the presence in the maternal serum of antibodies with titers which were uniformly lethal when only 500 cc. of blood were used. There is no doubt that there is some degree of toxicity when the exchange transfusion is done too rapidly and a temporary hypocalcemia results. This is readily counteracted by the cautious administration of calcium gluconate.\* If the infants show no hypocalcemic symptoms at the termination of the procedure no delayed action of citrate need be feared and no calcium need be administered. The other possible effect of the citrate, namely, to produce an alkalosis, would be expected to be salutary rather than harmful since an alkaline pH may tend to prevent serologic clumping and promote excretion of the products of hemolysis. One infant (case 15) died from pyemia, possibly as a result of infection introduced through the use of bank blood, and this is the only fatality that could conceivably be attributed to the treatment itself.

With regard to the technic of the procedure, the method used by us, besides being simple, is safe. We have had no operative mortality in a series of 40 transfusions performed to date. The use of heparin does not appear to be harmful or dangerous since it causes no tendency to bleed except from damaged or cut blood vessels and the heparin effect is nullified by the time the procedure is completed. Different methods of performing exchange transfusions have been suggested by other workers. With regard to the syringe method of Wallerstein,<sup>21</sup> this does not lend itself to the use of large amounts of blood except perhaps for operators with considerable experience and a high degree of technical skill. Some objections have also been raised to the use of the sagittal sinus as the avenue for withdrawing blood. The ingenious umbilical catheter method of Diamond<sup>22</sup> has been widely used and has been considered by some workers to be simpler than the method described by us. Recently, a modification of Diamond's original method has been devised whereby the catheter is inserted through an incision into the femoral vein at the groin instead of through the umbilical vessels.<sup>23</sup> The theoretic objection to the catheter method may be raised that it is a blind procedure and would appear to be tiring to the operators, since syringes must be continuously used to aspirate as well as to inject the blood. More important the method is somewhat dangerous since we

\* This is introduced slowly and always directly through the infusion cannula. It is never injected into the tubing.

know of at least two deaths from air-embolism that have occurred, and others in which death resulted from thrombosis and from hemorrhage into the peritoneal cavity. Also, technical failures have occurred even in experienced hands when the umbilical vessels could not be catheterized. Furthermore, the procedure usually cannot be carried out after twenty-four hours when the umbilical vessels close up. On the other hand, in our own series of over 40 exchange transfusions performed by using the radial artery for bleeding and the saphenous vein for the infusion, we have not had a single technical failure or operative mortality.

#### SUMMARY

1 In the authors' technic of exchange transfusion, citrated blood is introduced into the saphenous vein at the ankle and the infant's blood simultaneously with drawn from the radial artery at the wrist, coagulation being prevented by the administration of small amounts of heparin. The procedure besides being simple, is safe, there having been no operative mortality in more than 40 transfusions.

2 The results of exchange transfusion therapy in erythroblastosis in our first 28 cases are presented. Of these 28 cases, 16 were very severe and almost certainly would have been lethal if left untreated, 6 were of moderate severity, and 6 were mild. Only 7 of the infants died, and the available data indicate that the mortality would have been at least twice as high had the usual treatment with simple transfusions been given.

3 Aside from its greater efficacy in reducing mortality, exchange transfusion is more efficient, so that supplementary treatment is not required as a rule.

4 Fresh blood should be used instead of bank blood because of its greater survival time and smaller likelihood of introducing infection.

5 All infants who have survived have developed normally both physically and mentally and have shown no sequelae of liver or brain damage.

6 The most reliable index of the severity of the disease in the erythroblastic infant is provided by antenatal titrations of the maternal univalent Rh antibodies, as well as by tests for the presence of univalent antibodies in the infant's blood.

# RECENT STUDIES OF MULTIPLE MYELOMA STERNAL AND RIB PUNCTURE AND THE RESULTS OF TREATMENT WITH STILBAMIDINE

By SIMON PROPP, M D , L WHITTINGTON GORHAM, M D , AND SAMUEL KANTOR, M D

**M**ULTIPLE MYELOMA is commonly known as a malignant disease characterized by bone pain, deformity and abnormal fragility of the osseous system, cachexia, and Bence-Jones proteinuria. The tumors tend to be multiple. They are found most frequently in the spine, ribs, skull, bones of the shoulder girdle, pelvis, sternum and upper ends of the humeri and femora, where active blood formation occurs in the adult.

In 1845, Bence-Jones<sup>1</sup> found an unusual protein in the urine of a patient who complained of pain in the chest, back, and loins. This protein, which coagulated at 55 to 60 C. and redissolved upon boiling, has since been known by the name of the discoverer. Von Rustizky,<sup>2</sup> in 1873, first described a condition with multiple tumors of the bones which consisted of proliferating elements of bone marrow, under the title *Multiples Myelom*. Kahler<sup>3</sup> associated Bence-Jones proteinuria with multiple myeloma in 1889. The term *Kahler's disease* is frequently used as a synonym for this condition.

The pathology of multiple myeloma has been considered to be that of a neoplasm of the bone marrow in which the cytology varies depending upon the type of marrow cell involved. There is a diffuse proliferation of the malignant cells within the marrow. Arkinson<sup>4</sup> has summarized 643 cases of multiple myeloma. Of these 207 were classified as plasmacytoma, 27 myeloblastoma, 24 myelocytoma, 16 lymphocytoma, 5 erythroblastoma, 32 mixed, and 332 were unclassified. More recently, since the advent of the use of sternal marrow aspiration for diagnosis, reports on multiple myeloma have been almost entirely of the plasma cell type and there has been a definite trend to regard this disease as of plasma cell origin only.<sup>5, 6</sup>

The laboratory findings useful in diagnosis may be listed as follows: Bence-Jones proteinuria, hyperglobulinemia, excessive rouleaux formation of erythrocytes with clumping in Hayem's solution, and rapid sedimentation rate, osteoporosis by x-ray, hypercalcemia with normal or moderately elevated alkaline phosphatase and serum phosphorus values, anemia, myeloma cells\* in the peripheral blood, and myeloma cells in marrow aspiration. The latter finding has come to be regarded as pathognomonic of this disease. A positive marrow aspiration or surgical biopsy is necessary to establish the diagnosis.

The course of multiple myeloma is progressively fatal over a period of a few

From the Department of Medicine, Albany Medical College, Albany, New York.

Presented in part at the Western New York Regional Meeting of the American College of Physicians, Syracuse, New York, October 28, 1947.

Supported in part by a grant from the Winthrop Research Fund of the Albany Medical College.

\* The term myeloma cell in this article is used interchangeably with plasma cell to denote the series of dysplastic plasma cells observed in the bone marrow in multiple myeloma.

months to six years or longer from the time the diagnosis is made.<sup>5</sup> Treatment has been palliative. Roentgen therapy, nitrogen mustard, and radioactive phosphorus have shown no curative value. Snapper<sup>7, 8</sup> has introduced an interesting new chemotherapeutic agent in the treatment of this disease. He has apparently obtained relief of pain repeatedly in patients with multiple myeloma by the use of stilbamidine and pentamidine. Stilbamidine has proved very effective in treating visceral leishmaniasis. Because this disease and multiple myeloma are accompanied by hyperglobulinemia, it was reasoned empirically that stilbamidine might be of value in both. Kopac<sup>9</sup> has indicated that stilbamidine may act on nucleoproteins by demonstrating, *in vitro*, dissociation of protamine-ribonucleate complexes, the stilbamidine releasing protamine and simultaneously binding nucleic acids. Snapper has shown that following treatment of patients with multiple myeloma with stilbamidine, on a low animal protein diet, large basophilic inclusion bodies appeared in a high percentage of the myeloma cells. These were produced only in the presence of hyperglobulinemia or Bence-Jones proteinuria and appeared in 12 of 13 patients with increased blood globulin.<sup>10</sup> He has demonstrated that these inclusion bodies contained ribose nucleic acid, by studying the action of ribonuclease on the granules and by the use of the quartz microscope.<sup>11</sup> Stilbamidine was found by analysis in myeloma tissue obtained at postmortem examination eight days after completion of a course of this drug. He has advanced the theory that stilbamidine reacts with the cytoplasmic nucleoproteins of myeloma cells only, and not with nucleoproteins of other cells. A high protein diet, according to Snapper's theory, interferes with this reaction. He has suggested that pain is relieved because myeloma cell proliferation is arrested. Lack of expansion of osteolytic lesions for some time after cessation of treatment was demonstrated in some patients. This occurred despite the fact that the percentage of myeloma cells in the marrow smears was not shown to decrease. No changes in the myeloma cells were found after treatment with pentamidine, although relief of pain was obtained.

A feeling of formication about the face was common accompanying the injections of stilbamidine. A high incidence of dissociated anesthesia of the trigeminal nerve occurred two and a half to five months following treatment. This caused considerable distress in the form of severe persistent itching in only one of Snapper's patients. In most cases the discomfort gradually subsided. No toxic effects were produced on the liver or hematopoietic system. Renal failure was precipitated in two cases and caution was advocated in treating patients with renal damage and insufficiency.<sup>1</sup>

Ten out of eleven patients treated only with stilbamidine by Snapper were relieved of pain.<sup>12</sup> Pentamidine was used successfully in the one case in which stilbamidine failed. In two cases pentamidine was ineffective but subsequent use of stilbamidine caused the pain to disappear. Recurrence of pain required repetition of stilbamidine treatment and it was emphasized that although progress of the disease was temporarily checked no cure was obtained.

This article deals with a study of six cases of multiple myeloma admitted to the Albany Hospital within a relatively short period of time. An opportunity was presented to study myeloma cells before and after treatment with stilbamidine, and to observe the clinical effects of this drug.

## METHODS

Each case received a complete hospital work-up with appropriate laboratory and x-ray studies. Sternal marrow aspiration was done in all cases before and after treatment with stilbamidine. In addition, rib marrow punctures\* were performed on four occasions. Because of the great dependence placed on marrow puncture in the diagnosis of multiple myeloma, a more elaborate technic was developed which differed somewhat from that previously described.<sup>14</sup> Changes in procedure consisted in using heparin solution and 1 cc syringes for marrow aspiration. Heparin solution containing ten units per 1 cc † was used in sufficient amount to wet the syringe only. This syringe was then utilized to aspirate 0.2 cc of marrow fluid. The heparin prevented clotting, and subsequent steps could be carried out at the leisure of the operator. Coverslip smears were made directly from the marrow fluid without mixing. A cresyl blue wet smear and two supravital smears were then made. The fluid remaining was ejected onto a hollow slide. Marrow bits were identified by tilting the slide and these were picked up with pipets and smears repeated. The marrow mixture was then placed in a Wintrobe hematocrit tube, centrifuged, and a third set of preparations made from the buffy layer. The dry coverslip smears were subsequently stained with Wright's stain and a peroxidase-Wright's stain was done on a selected smear. This method of procedure gave three possibilities of securing a representative sample of marrow cells, and precluded the chance of missing the diagnostic picture from chance selection of material for smears, dilution with sinusoidal blood, and rapid clot formation in the aspirating syringe.

Rib puncture was performed in the scapular line. The skin and periosteum were anesthetized with procaine in a manner similar to that employed in sternal puncture. The margins of the rib were grasped between the thumb and index finger to ascertain the rib center. A sternal puncture needle 1.5 cm or less in length was used because of the possible danger of entering the pleural cavity. ‡ The center of the rib was bored with a rotary motion of the needle and the marrow cavity entered in a fashion similar to sternal puncture. The same preparations of marrow smears were made as enumerated above §.

\* Rib marrow puncture was first performed on one case suspected of rib malignancy immediately post mortem. The procedure was so simple and the results so satisfactory that it was performed later on a patient diagnosed clinically as multiple myeloma when sternal puncture was unsuccessful. A second sternal puncture and the rib puncture which was done in an area termed pathologic by the roentgenologist proved to contain normal bone marrow. The patient subsequently recovered. Since then rib punctures have been performed on sixteen patients and excellent marrow preparations obtained. A requisite for rib puncture is the careful palpation of the selected rib. Puncture should never be done if the rib is not easily palpable.

† Lilly's solution of sodium heparin.

‡ It was found by puncturing ribs during post mortem examinations that if considerable force were exerted the tip of a 1.5 cm needle could be forced through the parietal pleura of a thin person. A 1 cm needle could not be made to penetrate completely through the rib. A very definite give was usually experienced when the outer thin bony plate of a rib was pierced and the marrow cavity entered. This sensation was not invariably felt however so that aspiration was always attempted when the needle was firmly fixed in the bone. Then the needle was slowly advanced until marrow fluid was obtained or the sensation of entering the marrow cavity experienced.

§ Comparison of rib and sternal preparations have shown a similar marrow picture in 13 instances when both were done immediately following each other. Variations in amount of marrow material

The cases of multiple myeloma were treated with stilbamidine according to Snapper's method, as follows. The stilbamidine was dissolved in 10 cc of sterile distilled water and used immediately. Injections were given intravenously, starting with a dose of 50 mg. One hundred mg were given the following day, and then 150 mg daily for a total of 20 treatments which constituted the usual course. Atropine sulfate Gr 1/150 was given hypodermically 30 minutes before each injection to prevent or minimize immediate vasomotor reactions as recommended by Snapper. The total dosages of stilbamidine and the diets given to each patient are listed in table 2.

The clinical and laboratory findings and therapeutic results are illustrated in the following case histories.

#### CASE I

A S, a 61 year old white male office worker, was admitted to the Albany Hospital on Jan 7 1947. He had been ill for 3 months with unexplained fever. Two weeks before his hospital admission he developed pain in his left chest which was aggravated by cough and deep breathing. Physical examination revealed a fever of  $101^{\circ}$  and evidence of pneumonia in the left lower lobe which was confirmed by x-ray. The liver was enlarged and tender. The heart had irregular rhythm and there was a loud blowing apical systolic murmur. An electrocardiogram revealed auricular fibrillation and low T waves with slurring of QRS in the standard leads indicating myocardial damage. Hemoglobin was 7.5 Gm, red blood cells 2,000,000, white blood cells 8,150, segmented neutrophils 80 per cent, lymphocytes 14 per cent, and monocytes 6 per cent. Erythrocyte sedimentation rate Wintrobe was 10 mm in one hour.

The patient's pneumonia was treated effectively with penicillin and three 500 cc blood transfusions. He developed a nonpurulent, sterile, pleural effusion. Abnormal clumping of erythrocytes was noted on routine blood counting and because of this finding he was studied for multiple myeloma. The urine was positive for Bence Jones protein and showed a 1 plus albumin. Serum protein was 11.5 Gm per cent total with albumin 1.6 and globulin 9.9 Gm per cent, an A-G ratio of 0.16. Serum calcium was 11.9 mg per cent, phosphorus 3.2 mg per cent, alkaline phosphatase 3.9 Bodansky units, and NPN 60 mg per cent. X-ray examinations of the skull and ribs were normal. Sternal puncture revealed marked replacement of normal marrow elements by plasma cells. These made up 91 per cent of a 500 white cell differential count. This established the diagnosis of multiple myeloma.

Treatment was carried out with stilbamidine. Eighteen injections totaling 2.7 Gm were administered. Because of the poor nutritional state of the patient no restriction of protein was ordered. Unpleasant effects of the injections consisted of transient prickly feelings about the mouth, eyes and ears at the time of treatment and recurrent nausea and vomiting. These manifestations were not severe. Sternal puncture following the course of stilbamidine showed that 34 per cent of cells in the marrow smears were of the myeloma type. Azurophilic granulation was noted in the cytoplasm of some of these cells but no basophilic inclusion bodies were found.

The patient was discharged without improvement in his general condition. He subsequently expired on May 15 1947, 3 months from the time his treatment was concluded. No autopsy was obtained.

#### COMMENT

The diagnosis of multiple myeloma was only suspected in this case because of the abnormal clumping of erythrocytes noted in Hayem's solution in a routine blood count. His first presenting symptom of unexplained fever without pain was atypical. Confirmatory laboratory findings of hyperglobulinemia and Bence-Jones proteinuria were offset by negative x-ray examinations of skull and ribs. Diagnosis was established by sternal puncture. Treatment with stilbamidine without pro-

---

however have been observed. Further studies on rib puncture as a procedure to complement or supplement sternal puncture are being made.

tein restriction failed to effect a remission in the course of the disease or to produce basophilic granulation in the cytoplasm of the cells although hyperglobulinemia was present

# CASE 2

R. L., a 58 year old Italian male, was admitted to the Albany Hospital on January 28, 1947 with a chief complaint of vertigo. For ten days prior to admission he had repeated, transient attacks of dizziness and weakness and for six months had suffered from generalized headaches. There was a weight loss of 15 pounds during this period. He had had an acute infection in the right ear three weeks before admission,

FIGS 1-3 X RAYS OF SKULL, CASE 2, R. L.

FIG 1 January 29 1947 before treatment with stilbamidine

which had subsided. Examination revealed moderate tenderness over the left temporal region anterior to the ear. The Romberg test was strongly positive with the patient falling to the right. Blood pressure was 160 mm. of mercury systolic and 100 mm. diastolic. A routine x-ray of the skull showed numerous small punched-out areas of decreased density (fig 1). Further studies of the osseous system revealed evidence of active bone destruction in the 5th lumbar vertebra and some compression of the second and third lumbar segments. Laboratory examinations showed hemoglobin 13 grams, red blood cells 4,400,000, white cells 10,000 with a normal differential count, blood Wassermann negative, urine normal, total serum protein 12.1 Gm per cent, albumin 3.7 Gm per cent, and globulin 8.4 Gm per cent with an A-G ratio of 0.4. Serum calcium 10.5 mg per cent, phosphorus 3.8 mg per cent, alkaline phosphatase 3.6 Bodansky units, NPN 39 mg per cent, creatinine 0.9 mg per cent. No Bence Jones protein was found on repeated tests. Sternal puncture preparations contained 19.5 per cent plasma cells.

The patient was given a course of 20 injections of stilbamidine totaling 2.85 Gm. The diet was not restricted. He complained of burning of the skin, lacrimation, salivation, bilateral tinnitus and restlessness as an immediate reaction to the drug administration. These complaints subsided within a few minutes following the injections. Four weeks following treatment a sternal puncture revealed a reduction of myeloma cells to 6.2 per cent. The majority of these cells, 83.8 per cent, showed large basophilic inclusion bodies in the cytoplasm which were identical with those described by Snapper.<sup>8</sup> A roentgenogram of the skull indicated a definite increase in the areas of decreased density (fig. 2). Subjectively the patient felt generally improved, and the headaches and dizziness were relieved. Five weeks after completion of his first course of stilbamidine he had a recurrence of severe generalized headaches and aching pain in the

Fig. 2. April 3, 1947, five weeks after completion of first course of stilbamidine

lumbar spine. A second course of the drug, consisting of 1.35 Gm, was given over a period of ten days with the patient on a low animal protein diet. Relief of symptoms occurred and he returned to light work. Seven weeks after this course of treatment he complained of numbness about the mouth involving most of the face. No neurologic changes were noted. Later, intense burning in this region occurred, particularly at night. This still persisted after six months of observation. Rib puncture on Sept. 9, 1947, six and one half months following his first treatment and four and one half months after his second course of stilbamidine, revealed 58.8 per cent myeloma cells. Basophilic inclusion bodies were still present in 54 per cent of the cells. There were 2.3 per cent plasmablasts. Skull x-ray at this time showed further increase in the osteolytic lesions (fig. 3).

#### COMMENT

The clue to diagnosis in this case was obtained from an x-ray of the skull taken because of the patient's complaints of vertigo and headaches. The possibility of

multiple myeloma had not been previously entertained. Further osseous lesions in the lumbar vertebrae and hyperglobulinemia were confirmatory evidence. Sternal puncture established the diagnosis of multiple myeloma.

Treatment with stilbamidine without restriction of animal protein not only produced a remission of symptoms but also caused typical basophilic cytoplasmic inclusions in the majority of myeloma cells. This occurred at a time when osteoporotic lesions in the skull were increasing in size. A severe persistent trigeminal neuropathy followed a second course of treatment. Basophilic inclusion bodies

FIG. 3 September 4, 1947: six months after first course and four months after second course of stilbamidine.

were observed in the myeloma cells obtained from rib puncture four and one half months after treatment was concluded.

### CASE 3

C. S. H., a 47-year-old white male was admitted to the Albany Hospital on Feb. 26, 1947. He had been ill for 9 months with pain in his ribs, progressive weakness and fatigue, loss of weight and failing vision. He was told that he was anemic four months before admission to the hospital. Examination revealed a pale, thin patient who appeared chronically ill. There was tenderness to pressure over the lower ribs bilaterally. There was a soft, blowing apical cardiac murmur. The liver edge was palpable two fingers below the costal margin. Ophthalmic examination revealed presbyopia only.

*Laboratory studies* Positive test for Bence Jones protein and 4 plus albuminuria, hemoglobin 10 Gm, red blood cells 3,320,000, white blood cells 9,300 with a normal differential count, Wintrobe sedimentation rate 12 mm in one hour blood Wassermann negative total serum protein 5.6 Gm per cent with an A-G ratio of 2.5 NPN 30 mg per cent calcium 10.4 mg per cent phosphorus 3.2 mg per cent and alkaline phosphatase 4.2 Bodansky units X-rays of the skull and ribs were reported as being normal. A second roentgenogram of the ribs showed a suggestion of metastatic tumor on the lower left. Sternal puncture revealed that 23 per cent of marrow cells were of the large plasma cell type.

The patient was placed on a low animal protein diet and given a course of stilbamidine totaling 2.85 Gm. He also received two 500 cc blood transfusions. Sternal puncture was repeated after 2.55 Gm of stilbamidine or 18 injections had been administered. The marrow contained 43.4 per cent myeloma cells of which the great majority (82.9 per cent) contained basophilic inclusion bodies. At the conclusion of treatment hemoglobin was 9.5 Gm, red blood cells 4,160,000 and white blood cells 6,800 with a normal differential count.

This patient improved considerably. The pain in his ribs subsided, his vision improved and he gained in strength. He returned home and reported in six weeks by letter that he felt fine. Follow up of this patient revealed that two months after treatment he was relieved of pain and felt well except for a general skin rash and a sore tongue. His doctor reported that there was, however, a progressive decline in his general state. Retreatment was advised but the patient had moved away and the referring doctor was unable to locate his new residence. A follow up obtained by letter, however, written on Dec. 25, 1947, indicated that the patient was still ambulatory, but otherwise totally incapacitated by his illness.

#### COMMENT

This patient's symptomatology fitted the clinical picture of multiple myeloma. Bence-Jones proteinuria and anemia were the positive laboratory findings and x-rays were negative. There was no hyperglobulinemia. Sternal puncture findings were pathognomonic.

Stilbamidine treatment with a low animal protein diet plus transfusions improved this patient symptomatically and typical basophilic inclusion bodies were found in the majority of the myeloma cells, although the relative percentage of the tumor cells had definitely increased in the marrow. The treatment did not, however, have any sustained effect upon his general condition.

#### CASE 4

A W., a 61 year old male office manager, was admitted to the Albany Hospital on Jan. 12, 1947, with the chief complaint of an infection in his nose of one week's duration. He was a known diabetic who had been well controlled with diet and insulin for 30 years.

Examination revealed impetiginous lesions of the nose and forehead, a blood pressure of 170 mm. of mercury systolic and 80 mm. diastolic, and a palpable liver felt three fingers below the costal margin.

Urinalysis was normal except for a trace of sugar. Blood hemoglobin was 10 Gm, red blood cells 2,930,000, white blood cells 6,900, segmented neutrophils 71 per cent, lymphocytes 27 per cent, monocytes 2 per cent. NPN was 38 mg per cent and the blood Wassermann was negative. Total protein taken for investigation of liver function, was 10.7 Gm per cent with albumin 2.1 Gm per cent and globulin 8.6 Gm per cent, an A-G ratio of 0.24. Because of the hyperglobulinemia further studies were done. Urine positive for Bence Jones protein, clumping of erythrocytes was observed in Hayem's solution, and Wintrobe sedimentation rate was 61 mm. in one hour. Sternal puncture on Jan. 23, revealed 14 per cent large plasma cells and a marked reduction in erythroid and myeloid cells. A second sternal puncture at a higher level showed similar findings.

A diagnosis of multiple myeloma was made but because the patient was asymptomatic he was discharged from the hospital. Five months later he was readmitted because of a severe vaccinia. At this time, he complained of pain in his right hip but x-ray examination of his pelvis was normal. He was again discharged but shortly afterward began to have severe pain in the left chest in the region of the

fifth to the ninth ribs. He also suffered from diplopia. X-ray examination at this time showed evidence of bone destruction in the ribs. He was readmitted on July 17, 1947, for treatment with stilbamidine because of persistent bone pain. Examination revealed weakness of the left external rectus ocular muscle, with inability to move the left eye laterally. The liver was still enlarged. The urine contained 2 to 3 plus albumin but no Bence Jones protein. Hemoglobin was 9.5 Gm, red blood cells 3,200,000, white blood cells 6,300 segmented neutrophils 71 per cent, NPN was 42 mg per cent, total protein 9.1 Gm per cent, with albumin 2.2 Gm per cent and globulin 6.9 Gm per cent, an A-G ratio of 0.32.

The patient received a course of 20 injections totaling 2.85 Gm of stilbamidine from July 18 to Aug. 9. The diet contained 2,600 calories with 97 Gm of protein which was qualitatively unrestricted. Immediate reactions to the treatment were a burning about the mouth sometimes extending into the eyes, which was only momentary and nausea and at times vomiting which were delayed until later in the day. The diplopia and bone pain were unrelieved. Sternal and rib puncture on Aug. 12, showed a myelophthisic marrow with 61.2 per cent myeloma cells. No basophilic inclusion bodies were observed. The patient was then placed on a low animal protein diet and a total of 1.5 Gm of stilbamidine was administered in a course of ten injections from Aug. 15 to 27. There was no relief of pain. Puncture of the right eighth rib was performed at this time and no change in the marrow picture was found. There were no basophilic inclusion bodies in the myeloma cells.

On Sept. 10, 1947, a prefrontal lobotomy was performed for relief of pain. The patient expired post-operatively.

Autopsy confirmed the diagnosis of multiple myeloma. Infiltrations of plasma cells were noted in the liver.

#### COMMENT

The diagnosis of multiple myeloma was made during the hospitalization of this patient for impetigo and diabetes mellitus, because of the presence of hepatomegaly. The findings of hyperglobulinemia, Bence-Jones protein, clumping of erythrocytes in Hayem's solution and positive sternal puncture complete the diagnostic picture although the patient had no symptoms of the disease and x-ray studies of the bones were negative.

Treatment with a full course of stilbamidine without a low animal protein diet failed to relieve pain or effect the myeloma cells. A second course of 1.5 Gm of stilbamidine on a low animal protein diet also did not alleviate pain or produce basophilic inclusion bodies in the myeloma cells. Failure of treatment thus occurred despite the presence of both hyperglobulinemia and Bence-Jones proteinuria.

#### CASE 5

A. V., a white farmer, 72, was admitted to the Albany Hospital on Aug. 5, 1947, because of pain in the back, left hip and left leg of six months duration. The pain in the back and left hip occurred after a fall. About one month before admission the pain began to radiate down the medial aspect of the left leg. The pain was intermittent, sharp and worse at night. The patient also had frequent nose bleeds since the onset of his illness.

Physical examination showed emaciation. The skin was dry and loose. Blood pressure was 158 mm of mercury systolic and 70 mm diastolic. There was tenderness over the fourth right rib. The liver was enlarged and could be palpated two fingers below the costal margin. There was diminished sensation to light touch along the medial aspect of the left thigh and calf. The left patellar reflex was reduced.

The urine contained 3 plus albumin and many hyaline casts but no Bence Jones protein. Hemoglobin was 8.5 Gm, red blood cells were 2,860,000 and white blood cells were 10,150. On Aug. 6, the white blood cells were 12,200 with segmented neutrophils 48 per cent and lymphocytes 52 per cent. The blood Wassermann was negative. Total plasma protein was 12.7 Gm per cent with albumin 2.3 Gm per cent and globulin 10.4 Gm per cent, an A-G ratio of 0.22. Serum could not be obtained and clot retraction could not be studied because the blood rapidly formed a gel and no fluid portion remained. The clotting time was one minute and 18 seconds, coagulation time three minutes and platelet count 157,000. Clumping

of erythrocytes occurred in Hayem's solution. X rays revealed many small oval areas of lessened density throughout the skull and in the upper third of the left humerus. Myelogram showed bilateral deformities opposite lumbar vertebrae 3 and 4 more marked on the left which was consistent with a displaced disc. Spinal fluid contained 60 mgs per cent protein and the Wassermann test was negative. Sternal and rib punctures on Aug. 9 were diagnostic of multiple myeloma. There were 45.6 per cent plasma cells. Of these 1.2 per cent were plasmablasts, and 4.8 per cent were young forms. There was great variation in size and appearance of the cells. Syncytial sheets of small cells with nuclei placed centrally, or nearly so and uniformly basophilic cytoplasm were seen which resembled basophilic normoblasts. Larger cells had typically eccentric nuclei and abundant basophilic cytoplasm characteristic of plasma cell myeloma. Subsequently a few large plasma cells of similar type were observed in the peripheral blood smear.

The patient's condition deteriorated rapidly. On the third hospital day he was given 500 cc. of blood by indirect transfusion. On the sixth day he became drowsy, stopped taking fluids and then gradually became comatose. NPN was 72 mg per cent. On Aug. 15, NPN was 58 mg per cent, and plasma  $\text{CO}_2$  43 volumes per cent. Fifty mg. of stilbamidine were given intravenously, and 100 mg. the following day. The patient expired in coma on the eleventh hospital day.

Autopsy revealed involvement of lumbar vertebrae, skull and sternum with plasma cell myeloma. An unusual phenomenon was the finding of a complete cast of the heart and larger vessels formed by a firm gel composed of blood plasma.

### COMMENT

This was a typical, malignant type of multiple myeloma showing a fully developed symptomatic and pathologic picture. Sternal and rib puncture confirmed the diagnosis. The marrow cytology was interesting because of the presence of small myeloma cells resembling basophilic normoblasts. Treatment with stilbamidine was attempted only because of the obviously bad prognosis. Autopsy confirmed the diagnosis and a striking finding was the presence of a cast of the heart and vascular system consisting of a firm gel of the blood plasma.

### CASE 6

E. J. B., an 85 year old single white female, was admitted to the Albany Hospital on Nov. 22, 1947. She had complained of pain in her back in the region of the lower ribs which radiated anteriorly about her chest, for four months. The pain was almost constant but varied in severity. It was aggravated by motion. She had lost weight and strength and for the month prior to admission, had suffered from anorexia, dyspnea and recurrent vomiting. Physical examination showed a very thin, dehydrated patient who was tender over the lower thoracic vertebrae. The heart was enlarged and systolic murmurs were heard over the aortic and mitral areas. The clinical impression was osteomalacia or metastatic malignancy and arteriosclerotic heart disease.

The urine showed only a trace of albumin and tests were negative for Bence Jones protein. Hemoglobin was 8.0 Gm., red blood cells 2,650,000, white blood cells 8,750, segmented neutrophils 71 per cent, band neutrophils 1 per cent, eosinophils 1 per cent, basophils 1 per cent, and lymphocytes 26 per cent. Wintrobe erythrocyte sedimentation rate was 66 mm. in one hour. The blood Wassermann was negative. Serum phosphorus was 2.2 mg per cent, alkaline phosphatase 2.1 Bodansky units, serum calcium 11.3 mg per cent, and NPN 30 mg per cent. Total serum protein was 7.7 Gm. per cent of which albumin was 3.2 and globulin 4.5. An A-G ratio of 0.7. X ray examinations revealed a partial collapse of the bodies of thoracic vertebrae 7, 10, 11 and 12 with marked atrophic changes in all the vertebral bodies. There were multiple small areas of localized bone destruction throughout the ribs and in both scapulae. The 6th rib was fractured in the axillary line on the left. There were multiple minute areas of lessened density distributed throughout the skull. Sternal and rib aspirations were performed on Nov. 26 and the marrow smears revealed 25.4 per cent plasma cells and 0.4 per cent plasmablasts. This established the diagnosis of multiple myeloma. The patient was placed on a low animal protein diet and given a course of 12 injections of stilbamidine totaling 1.65 Gm. There was no reaction to the drug. She continued to have constant severe pain in the back and nausea and vomiting. Her general condition gradually grew worse and death occurred

on the twenty-second hospital day Autopsy revealed multiple myeloma of the plasma cell type involving the ribs sternum and vertebrae Smears of the sternal marrow obtained post mortem showed 21.4 per cent plasma cells and 0.4 per cent plasmablasts No basophilic inclusion bodies were observed

#### COMMENT

This patient had multiple myeloma at the extreme age of 85 years The diagnosis was indicated by the clinical picture, x-ray findings, and hyperglobulinemia, and

was confirmed by marrow aspiration. Treatment with 1.65 Gm of stilbamidine failed to relieve pain or produce basophilic granulations in the myeloma cells, although hyperglobulinemia was present.

#### CYTOLOGY

The cytology of multiple myeloma has recently been described by Diggs and Sirridge.<sup>6</sup> Their findings were based on fifty-five cases of plasma cell myeloma. Support was given to the thesis that multiple myeloma is derived from plasma

cells arising from primitive reticulum as a specific strain of cells. The term myeloma cell was objected to because it inferred a specific type of cell peculiar to multiple myeloma only. Our observations on the cytology of the six cases being reported were similar to those of Diggs and Sirridge.

Our cases were entirely of the plasma cell type. In general, with Wright's stain, the following characteristics were noted. The cells were oval in shape, the nuclei eccentric, round and pachychromatic but not typically cart-wheel or Radkern. Variation in size occurred not only in the various patients but also in each individual case. The cytoplasm was abundant and minor differences in intensity of its basophilic substance were present in the different cases. Vacuolization of the cytoplasm was common, and a perinuclear clear zone was a prominent feature. In case 5, small cells with uniformly basophilic cytoplasm and centrally placed nuclei were noted, which resembled basophilic normoblasts (fig. 9). The usual type of plasma cell in normal marrow is shown in figure 4. A second type of plasma cell with more abundant, less deeply basophilic cytoplasm, without vacuoles and with a larger nucleus, observed in the same marrow smear, is illustrated in figure 5. The latter closely resembles the typical cells found in our cases of multiple myeloma (figs. 6, 7). Plasmablasts of large size with a definitely eccentric, large leptochromatic nucleus containing nucleoli, and comparatively little, basophilic cytoplasm, were observed in small numbers (fig. 10). The highest percentage of plasmablasts was 2.3, seen in case 2. Young plasma cells containing large, relatively immature nuclei without nucleoli, and more abundant cytoplasm than the blast form, constituted 4.8 per cent of the myeloma cells in case 5. Very large cells with multiple separate nuclei were seen in all cases. Mitotic figures were not numerous. Sheets of plasma cells were commonly observed in preparations made from marrow bits and occasionally in direct smears of unconcentrated marrow fluid (fig. 8). The plasma cells were uniformly peroxidase negative (fig. 11).

Supravital studies revealed a close similarity between the myeloma cells and large plasma cells seen in marrow smears made from patients with other conditions, and from normal marrow. The cells were large and oval, or round, with abundant cytoplasm and a distinct cell membrane. The nucleus was round and very definitely eccentric. Neutral red vacuoles of variable size were present external to the nucleus. These could be observed to enlarge as the preparations aged. Large mitochondria were a striking feature.<sup>18</sup> These were interspersed in the cytoplasm but were more abundant near the nucleus (fig. 12). The usual type of plasma cell seen in normal marrow was smaller and the mitochondria and neutral red vacuoles appeared to be less numerous and of smaller size.<sup>18</sup> However, a large type plasma cell was observed in one case of chronic aleukemic myelogenous leukemia treated with x-ray, which was indistinguishable from the typical plasma cell seen in the multiple myeloma patients.

After stilbamidine treatment, large basophilic inclusions were noted in the cytoplasm in the majority of the plasma cells stained with Wright's stain, in cases 2 and 3, (fig. 13, 14), while no inclusions were seen in the other four cases. No change was observed in cells stained by the peroxidase method. Although the

illustrated cell (fig 15) shows an increased size in neutral red vacuoles by supravital stain, this was not remarkable as compared to studies made prior to treatment

### DISCUSSION

The method of diagnosis of multiple myeloma in the cases reported is illustrated in table 1. The seven findings which are more pertinent to the diagnosis are listed

PHOTOMICROGRAPHS IN COLOR TAKEN FROM THE SAME MARROW SMEARS AS THE CORRESPONDING  
PHOTOMICROGRAPHS WITHOUT COLOR

Top row figs 4 5 6 Second row figs 7 8 9 ( $\times 450$ ) Third row figs 10 ( $\times 1410$ ) 11 13

together and collateral findings which are common to other conditions are placed in the lower section of the chart. The table shows in striking fashion an observation that is well-known, that the clinical picture of multiple myeloma is extremely variable. The only constant feature in all cases was the presence of a positive marrow aspiration. In one patient (case 3), the diagnosis was made by sternal puncture although only bone pain, Bence-Jones protein, and anemia were present. A clinical diagnosis was made prior to laboratory or x-ray studies in two cases. The clue to the diagnosis was found by the simple observation of clumping of erythrocytes

in Hayem's solution in one instance, by x-ray of the skull because of vertigo and headaches in a second, and from the finding of hyperglobulinemia while investigating the presence of hepatomegaly in a third case

The great value of marrow aspiration in the differential diagnosis of multiple myeloma makes a satisfactory technic for this procedure extremely important. A method has been described which utilized unconcentrated marrow fluid, selected marrow bits, and a concentration of marrow cells obtained by centrifugation. The selection of marrow bits produced the most satisfactory marrow smears. Rib puncture was used successfully to complement and supplement sternal aspiration. This was found to be a simple and usually painless procedure. One important

advantage is psychologic, the patient being unable to observe the details of the puncture. Caution must be used and no rib puncture should be done on a patient in whom the outlines of the rib are not definitely palpable.

The criteria upon which a diagnosis of multiple myeloma is made from marrow aspiration are not well defined. The number of plasma cells in the preparations is variable and reports have been as low as four per cent in one of the cases of Diggs and Sirridge<sup>6</sup> and three per cent in the series of Rosenthal and Vogel.<sup>17</sup> In normal marrow the percentage of plasma cells is usually less than 1 per cent. However, in other conditions, they may be present in greater numbers. \* It is felt that the con-

\* In our own studies a marrow of fatal agranulocytosis showed practically a complete replacement with plasma cells and lymphocytes.

tent of plasma cells in the marrow in diseases other than multiple myeloma may not have been adequately studied. A factor which can not be evaluated is the admixture of sinusoidal blood in preparations made directly from aspirated marrow.\* It is believed that the marrow picture is pathognomonic when the predominant cell type is the myeloma cell as described above. The presence of dysplastic cells, blasts, and young forms of the same cell line is also important. Masses of apparently proliferating cells are best found in preparations made from selected marrow bits. When the percentage of characteristic cells is low, consideration of the clinical

TABLE 2.—*Results of Treatment with Stilbamidine*

Case no	Stilbamidine treatment	Total dose grams	Diet	Basophilic inclusions in cells	Relief of pain	General effect	Final results

picture as a whole is felt to be essential to the diagnosis. This, of course, is always preferred, so that marrow puncture becomes only one of the criteria upon which diagnosis is based.

The thesis that multiple myeloma tissue is derived from a dysplastic line of plasma cells originating in the bone marrow is supported by our studies. All cases in this series are of the plasma cell type and plasmablasts, immature plasma cells, and dysplastic cells are described. A series of photo-micrographs (figs 4 to 15) offers objective evidence tending to confirm this theory.

Our observations confirm the original findings of Snapper that large basophilic inclusion bodies may be demonstrated in the cytoplasm of myeloma cells obtained

\* One patient with anemia due to chronic uremia revealed 10 per cent plasma cells in smears made from marrow bits when only an occasional plasma cell was seen in direct smears.

from bone marrow aspiration, in patients with multiple myeloma on a low animal protein diet, following treatment with stilbamidine. These basophilic bodies were not present prior to treatment. The two patients in our series who showed the granules obtained relief of pain. One patient was on a low animal protein diet while the diet of the second was not restricted. The latter patient showed typical basophilic granulation and a reduction in the percentage of plasma cells in marrow aspiration smears, and at the same time had a definite enlargement of osteolytic lesions in his skull. This fails to confirm the observation of Snapper that a low animal protein diet is essential for the production of basophilic granulation in the myeloma cells. The supposition that relief of pain is produced by an arrest of myeloma cell proliferation is also not substantiated. Complete failures to relieve pain or produce basophilic granules in the myeloma cells were recorded in three of our series of patients who had hyperglobulinemia. One was on a nonrestricted diet, and one received two courses of stilbamidine, the first without and the second with a low animal diet. The third patient was on a low animal protein diet.

Reactions to treatment with stilbamidine were transient except in one patient (case 3). He developed a trigeminal neuropathy which was still causing a severe burning sensation in his face after six months of observation. No dissociation of sensation occurred. Snapper reported an incidence of 10 cases of trigeminal neuropathy in a total of 18 patients treated with stilbamidine, and explained the mechanism as due to toxic degeneration of the principle sensory nucleus of the trigeminal nerve.<sup>13</sup> This caused severe and persistent itching which was disabling in character in only one of his patients. This subjective symptom ultimately disappeared in all of his patients. The objective findings of dissociated anesthesia were persistent.

#### SUMMARY

1. The value of bone marrow aspiration in the diagnosis of multiple myeloma was confirmed and discussed. This procedure should be utilized in all patients suspected of having this disease.

2. The importance of a reliable technic of studying bone marrow obtained by aspiration was stressed, and a method emphasizing certain important features described in detail.

3. The theory that multiple myeloma is derived from a dysplastic line of plasma cells originating in the bone marrow was supported by this study.

4. The original observation of Snapper has been confirmed, that after treatment of multiple myeloma patients with stilbamidine, large basophilic inclusion bodies can be demonstrated in the cytoplasm of a majority of myeloma cells obtained from bone marrow aspiration and stained by Wright's stain. This was produced on a nonrestricted as well as on a low animal protein diet.

5. Relief of pain was produced in two out of five patients with multiple myeloma treated with stilbamidine. One patient who was relieved of pain was on a low animal protein diet while the diet of the second was unrestricted. In both cases basophilic inclusion bodies appeared in the myeloma cells following treatment. Stilbamidine therapy failed to alleviate pain or to produce basophilic granulation in the myeloma cells in three patients who exhibited hyperglobulinemia.

- 6 Relief of pain and vertigo occurred in one patient treated with stilbamidine while osteolytic lesions were observed to enlarge by roentgenological examination
- 7 Trigeminal neuropathy with severe discomfort still continued six months following treatment in one patient
- 8 An arrest or remission in the course of the disease was not obtained in five cases of multiple myeloma treated with stilbamidine

# THE DISTRIBUTION OF HISTOCHEMICALLY DEMONSTRABLE GLYCOGEN IN HUMAN BLOOD AND BONE MARROW CELLS

By MAX WACHSTEIN, M D

RENEWED attention has recently been given to the glycogen content of the human blood Wagner,<sup>17</sup> confirming older observations in the literature,<sup>1 18</sup> found glycogen only in the granulated leukocytes by chemical estimation, while the other formed elements in normal blood did not contain this substance Increased amounts of glycogen were found in the blood of patients with myeloid leukemia, while in the blood of patients suffering from acute leukemia, as well as of those with chronic lymphatic leukemia, normal amounts of glycogen were present <sup>1 18</sup>

The particular usefulness of the periodic acid-Feulgen technic for the histochemical demonstration of polysaccharides (McManus,<sup>11</sup> Lillie,<sup>10</sup> Hotchkiss<sup>9</sup>), prompted an examination of human blood and bone marrow smears

## TECHNIC

Either air-dried blood and bone marrow smears, or films fixed in absolute alcohol were placed into a 0.5 per cent solution of periodic acid in water for five minutes Even slides several years old gave very satisfactory staining reactions After washing in tap water, the slides were immersed in Schiff's reagent, prepared according to Hotchkiss,<sup>9</sup> for fifteen minutes They were then rinsed in three changes of SO<sub>2</sub> containing water, each time for two minutes, and then washed for five minutes under tap water Harris hematoxylin was used as counterstain After the usual dehydration, slides were covered with a resin under cover slips In order to identify the stained substance as glycogen, alcohol-fixed blood and bone marrow films were first covered with saliva for 15-30 minutes at room temperature <sup>2</sup> After a short wash in distilled water, the above described staining technic was employed

## RESULTS

*Normal blood smears* Only the polymorphonuclear leukocytes and platelets showed consistent staining The cytoplasm of the polymorphonuclear leukocytes revealed a dark red to Bordeaux red uniform color (fig. 1) Occasionally it contained small dustlike and also somewhat coarse granules The nucleus was always stained At least 90 per cent of all polymorphonuclear leukocytes gave this staining reaction Eosinophiles in normal blood, as well as in films in which markedly enlarged amounts of these cells were present, showed faint staining of their cytoplasm The granules remained unstained Lymphocytes were mostly without staining However, some showed small granules in the cytoplasm Monocytes were either negative or showed only faint staining The thrombocytes consistently gave a positive reaction For the most part they showed a brilliantly stained center and a paler outer border

From the Laboratories of the St. Catherine's Hospital Brooklyn New York and the Division of Pathology, Mt. Sinai Hospital, New York New York

*Leukocytosis* In blood smears from patients suffering from marked infectious leukocytosis due to various causes, polymorphonuclear leukocytes, including the metamyelocytes, contained large amounts of cytoplasmic glycogen. The cytoplasm showed not only diffuse staining, but in some cells it appeared in coarser granules than commonly seen in the blood films of normal subjects.

*Infectious mononucleosis* The atypical lymphocytes were negative with the exception of some which contained dark red granules as seen in normal lymphocytes.

*Various anemias* In smears from patients with various anemias (erythroblastosis fetalis, Cooley's anemia, etc.) nucleated red cells, erythroblasts, as well as normoblasts, were negative.

FIG. 1. A blood film from a normal individual stained by the periodic acid-Schiff technic for glycogen. Two polymorphonuclear leukocytes show diffuse staining of the cytoplasm. The nuclei are counterstained with Harris hematoxylin.

*Lymphatic leukemia* The lymphocytes found in blood smears of patients suffering from lymphatic leukemia showed the same staining reaction as those in normal blood smears.

*Chronic myeloid leukemia* Myelocytes, metamyelocytes, and polymorphonuclear leukocytes showed the cytoplasmic polysaccharide reaction. Myelocytes took only a faint reddish color (fig. 2). The intensity of the reaction obviously increased with the maturation of the cells. Dark red granules and coarse stippling were fairly frequent in polymorphonuclear leukocytes.

*Acute myeloid leukemia* Most of the myeloblasts did not contain glycogen, while some cells, obviously still quite immature, revealed occasional dark red granules or even a brim of red-staining cytoplasm around the large immature nucleus. More mature myeloid elements showed the usual amount of glycogen.

*Blood smears from various animals* The polymorphonuclear (heterophile) leukocytes in the blood film of dogs, rabbits, guinea pigs and frogs showed considerable staining reaction. Only faint traces were demonstrable in the white cells of the rat and mouse.

*Smears from Lymph nodes* In films from tonsils and lymph nodes not involved by disease, the lymphocytes showed no trace of glycogen.

*Bone marrow* In films from bone marrow of normal individuals, as well as of those with various abnormal conditions, a behavior of the myeloid elements similar to that seen in the blood films of patients with chronic myeloid leukemia was observed. Myeloblasts were mostly negative. As the myeloid cells matured, the stain

FIG. 2. A blood film from a patient with chronic myeloid leukemia, stained by the periodic acid Schiff technic for glycogen. Three polymorphonuclear leukocytes—one juvenile cell and two myelocytes—are shown. The cytoplasmic staining is most pronounced in the mature cells.

ing reaction in the cytoplasm became more pronounced. Occasional myeloid cells showed coarse granules. Most nucleated red cells, including the typical megakaryoblasts of pernicious anemia, showed no staining reaction. A very occasional erythroblast revealed a faintly stained cytoplasm. Plasma cells as well as the atypical cells found in multiple myeloma, were mostly negative. A considerable proportion of the megakaryocytes gave a distinct reaction. The cytoplasm was coarsely stained. Only occasional megakaryocytes did not contain any stainable polysaccharides.

#### COMMENT

As far back as 1877, Ranvier<sup>12</sup> demonstrated glycogen in the leukocytes of the frog with the help of iodine. Ehrlich,<sup>6</sup> several years later, was the first to examine

films of human blood for its glycogen content. Since then a good number of papers dealing with the histochemical demonstration of glycogen have been published. The older literature has been extensively reviewed in Neukirch's<sup>12</sup> and Girardin's<sup>8</sup> contributions. So far, the following methods have been used for the demonstration of glycogen in blood cells:

1. *Iodine reaction*

(a) Dried films were exposed to iodine vapors (Ehrlich and Lazarus<sup>7</sup>). In normal blood films leukocytes are unstained, red blood cells take a brownish hue and platelets are stained. The leukocytes in exudates, however, show a strong reaction.

(b) Wet films were exposed to iodine vapors according to Zollikofer.<sup>22</sup> All neutrophilic leukocytes stain diffusely while some (about 20 per cent according to Girardin<sup>8</sup>) contain glycogen granules. As with Ehrlich's method the platelets are distinctly and the red blood cells faintly stained.

2. *Best's carmine method*

This method was modified by Neukirch<sup>12</sup> for blood films. All polymorphonuclear leukocytes in normal blood give a diffuse to fine granular staining. In addition the centers of the thrombocytes are stained. The other cells are unstained with the exception of occasional lymphocytes showing a few red granules. Neukirch found the eosinophilic granules positive in blood films and Arnold<sup>1</sup> in bone marrow section, while Girardin, using Neukirch's method, found them consistently negative.

3. *The Bauer-Feulgen stain* as well as a *silver technic*, have been used for bone marrow section of the normal rhesus monkey by Wislocki and Dempsey.<sup>21</sup> Glycogen was demonstrable in polymorphonuclear neutrophils and neutrophilic metamyelocytes but not in any other cells. In the circulating blood, as observed in sections of blood contained in the heart, glycogen was seen only in polymorphonuclear leukocytes.

As is well known, substances giving any of the reactions described above, can only be considered as glycogen if they can be digested by amylase. It has been repeatedly demonstrated that the carbohydrate-like substance found in the cells of purulent exudates can be digested by saliva.<sup>12</sup> According to Neukirch, however, with both the iodine or Best's carmine technic, the staining reaction in the leukocytes of the blood, as well as that in the platelets, is not prevented by previous treatment with saliva. Dempsey and Wislocki, on the other hand, using the Bauer-Feulgen technic, found the stainable substance in leukocytes digestible by saliva.

Further examination of the nature of the substance giving the reaction with the periodic acid-Schiff technic was therefore undertaken. By using periodic acid, polysaccharides are oxidized to polyaldehydes. The aldehyde group reacts with Schiff's reagent. Low molecular compounds such as simple sugars and hydroxyamino acids can also react with this reagent, while the pentose component of nucleic acid does not react (Hotchkiss).

No staining reaction was seen in air-dried or alcohol-fixed films without previous treatment with periodic acid, thus excluding the possibility that the reaction was due to preformed aldehyde groups. Since the reaction occurred after twenty-four hours of alcohol fixation it could not have been caused by the alcohol-soluble plasma. The substance was still present at room temperature (24-26°C) after immersion of the films up to 150 minutes in distilled water or saline solution. Therefore it appears unlikely that the reaction was due to the presence of simple low molecular water-soluble substances.

In order to prove that the stainable substance was really glycogen, blood films were subjected to digestion with saliva. A significant difference became apparent

when films were only air-dried or had been fixed with absolute alcohol. After fixation the stainable substance, in leukocytes as well as in platelets, disappeared fifteen to thirty minutes following salivary digestion at room temperature. In unfixed films, the diastatic effect of saliva was considerably less pronounced, although varying in intensity in different slides. Salivary digestion occurred to a varying degree in alcohol-fixed films from bone marrows as well as in the peripheral blood of patients with myeloid leukemia. In occasional films, the cells proved resistant to the diastatic enzyme.

The results of these experiments make it seem very probable that the substance giving the aldehyde reaction after treatment with periodic acid in blood cells is glycogen. The glycogen in hematic elements, however, is relatively resistant to salivary digestion, unless first treated with alcohol. This may be due to the fact that the cells contain the glycogen in some chemical combination, possibly with protein. Such an assumption was made many years ago by Best.<sup>3</sup> Willstaetter and Rhodewald<sup>19</sup> discuss the peculiar fact that the glycogen becomes more demonstrable in leukocytes of exudates than in the blood. Ehrlich thought that the leukocytes which migrate from the blood stream are being changed in such a way that after some time free glycogen occurs. According to Willstaetter and Rhodewald, it can be assumed that the glycogen is not present in its usual form but possibly in some absorption, or more probably, in chemical connection with the cell protein.

As has been previously found, employing iodine as well as Best's carmine, the platelets give a strong staining reaction. Moreover, in the bone marrow films most of the megakaryocytes are stained. This is obviously due to glycogen, since the staining reaction is prevented by digestion with saliva. In contrast, Wagner<sup>17</sup> found that the reducing substance which is formed after acid digestion of platelets was not digestible by yeast. He therefore concluded that it originated from ribonucleic acid rather than glycogen. By histochemical methods Wislocki, Bunting and Dempsey,<sup>21</sup> found some ribonucleoprotein in the cytoplasm of megakaryocytes.

The behavior of histochemically demonstrable glycogen resembles that of stainable oxydase. This, however, should not be expected to be of practical value for the differentiation of myeloid from lymphatic cells, since some myeloblasts as well as occasional lymphocytes reveal glycogen granules.

A certain parallel of the glycogen reaction in the leukocytes and the histochemically demonstrable phosphatase is quite obvious. Phosphatase activity becomes apparent in myelocytes.<sup>16</sup> The intensity of the phosphatase reaction increases with the maturation of the myeloid cell and is particularly prominent in films of patients with infectious diseases and in exudates. It was previously assumed that this increase in phosphatase may indicate an intensification of metabolic processes.<sup>16</sup> Glycogen is probably the main source of energy for the leukocytes.<sup>18, 22</sup> The importance of phosphate-splitting enzymes in the intermediary carbohydrate metabolism is well recognized. The histochemically demonstrable relationship between glycogen and phosphatase activity has recently been discussed by Dempsey and Wislocki.<sup>5</sup>

#### SUMMARY

By applying Schiff's reagent after periodic acid treatment to blood and bone marrow films, a cytoplasmic staining reaction is seen in some cells of the myeloid

series, as well as in megakaryocytes and platelets. The intensity of the staining reaction in the myeloid cells increases with their maturation. The staining reaction can be prevented altogether in alcohol-fixed films by salivary digestion, but only incompletely in air-dried films. The staining reaction is due to the presence of glycogen in some chemical association, possibly with protein.

# PYRIDOXINE DEFICIENT DIET AND DESOXYPYRIDOXINE IN THE THERAPY OF LYMPHOSARCOMA AND ACUTE LEUKEMIA IN MAN

By ALFRED GELFHORN, M D , AND LOGAN O JONES, M D

EVIDENCE from animal experimentation indicates that pyridoxine, a component of the vitamin B complex, is an essential factor for the maintenance and function of hematopoietic tissue. Severe anemia has been induced in dogs<sup>1</sup> and swine<sup>2</sup> on a pyridoxine deficient diet and the integrity of lymphoid tissue in rats has also been demonstrated to be dependent upon this vitamin.<sup>3-5</sup> The significance of pyridoxine in human nutrition is unknown inasmuch as no known deficiency state involving this vitamin alone has been described.<sup>6</sup> Recently, Stoerk reported that lymphosarcoma transplants failed to grow in mice maintained on a pyridoxine deficient diet, he further noted that established transplants of lymphosarcoma regressed when mice were placed on a pyridoxine deficient diet together with the specific vitamin antagonist, desoxypyridoxine.<sup>7</sup>

In the experiments reported in this paper, an attempt was made to induce a pyridoxine deficiency in man to determine any possible therapeutic effects in lymphosarcoma and acute leukemia. Although no significant clinical improvement resulted from the experimental therapeutic regimen, the results are of interest in that they indicate certain fundamental differences in the utilization of pyridoxine in lower animals and man.

## MATERIALS AND METHODS

Six patients were placed on a pyridoxine deficient diet and given desoxypyridoxine. Three patients had disseminated lymphosarcoma and 3 had acute leukemia. It was planned to keep the subjects on this diet for fourteen days. However, in several instances the caloric intake was limited so severely by the unpalatability of the diet that the regimen was of necessity discontinued earlier. The basic constituents of the diet were (a) vitamin-free casein,\* (b) gelatin, (c) sugar, (d) cornstarch, (e) unenriched cream of wheat, (f) butter, (g) artificial flavoring. The patients were also allowed carbonated drinks such as ginger ale and Coca-cola ad libitum, tea and coffee without cream or milk, and one serving of peaches or one apple per day. The dietician, working with this very limited number of foodstuffs, prepared cookies and puddings to provide some variety. However, all of the food had a chalky consistency and flavor which rapidly became extremely distasteful to the patients. Therefore, although an adequate amount of protein, carbohydrate and fat, as well as an adequate number of calories were provided, in only 2 of the patients was the diet completely consumed. In addition to the above, the

From the Departments of Pharmacology and Medicine, Columbia University College of Physicians and Surgeons and the Presbyterian Hospital, New York.

This work was supported by a grant from the American Cancer Society on recommendation of the Committee on Growth of the Vocational Research Council.

\* Labco Borden & New York

patients were given appropriate doses of thiamine, nicotinic acid, riboflavin and ascorbic acid as individual vitamins

Desoxypyridoxine\* was given to the first 2 patients studied in doses of 25 mg per Kg per day in three equally divided doses by mouth. Due to toxic manifestations which will be described later, the dose was progressively decreased to approximately 2.5 mg per Kg per day in the other patients of the series.

Disturbance of tryptophane metabolism as manifested by xanthurenic acid and kynurenine excretion in the urine has been reported in experimental animals on a pyridoxine deficient diet.<sup>8-10</sup> Daily 24 hour urine specimens were collected on 2 of the patients and xanthurenic acid determinations were made according to the technique described by Porter.<sup>9</sup>

### CASE REPORTS

**Case 1 D T** This 6 year old white boy had developed painless swelling at the base of his neck with associated fever, cough and wheezing respirations beginning four weeks before hospital entry. Aside from recurrent asthma and eczema his past history was negative. Examination revealed slight fever (100.2 F) wheezing but unlabored respirations hoarse cough generalized lymphadenopathy massive in left cervical and axillary regions and probably retroperitoneal as well with splenomegaly. Positive x ray findings were limited to the chest where a widened mediastinum and a large anterior mediastinal mass were noted. Blood studies revealed normochromic anemia a normal leukocyte count and differential and normal sternal bone marrow. Cervical node biopsy disclosed *lymphocytic lymphosarcoma*.

Following a four day course of methyl bis ( $\beta$ -chloroethyl) amine totalling 0.4 mg per Kg the temperature fell to normal appetite and weight increased hoarse cough disappeared and visible nodes regressed. Within the ensuing week lymphadenopathy recurred. Shortly thereafter the patient was placed on a pyridoxine free diet for four days together with the pyridoxine analogue desoxypyridoxine (2 mg per Kg per day) and 1.0 Gm l tryptophane — both in three equal daily doses. L tryptophane was given to accentuate any possible disturbance in the metabolism of this amino acid. Throughout this period appetite decreased markedly, concomitant weight loss of 0.5 Kg and continued enlargement of nodes with tracheal compression were noted. Of interest was the fact that the peripheral blood values remained unchanged and no xanthurenic acid was excreted in any of the four 24 hour urine specimens during these four days. Lymph node response to a second course of methyl bis ( $\beta$ -chloroethyl) amine administered at this time was minimal and the patient was discharged to receive radiotherapy at an institution nearer his home after a lapse of two weeks. Although therapeutic response to irradiation appeared to have been excellent one month later he developed recurrent epistaxis rectal bleeding and abdominal pain and died at home. The total duration of his illness had been approximately four months.

**Case 2 R C** This 52 year old white housewife was hospitalized for progressive painless enlargement of all superficial lymph nodes over a six months period with increasing nasal obstruction and hearing loss as well as pain in the right hip. Pertinent physical findings were some loss of hearing hyperplasia of pharyngeal lymphoid tissue in addition to generalized lymphadenopathy (including retroperitoneal area probably) hepatosplenomegaly and fever. Blood corpuscle counts and differential urinalysis liver function tests and x rays of chest and sinuses were normal. Fasting serum sugar was 58 mg per cent. An inguinal node biopsy revealed *reticulum-cell sarcoma*.

The patient received a single injection of 36.4 mg (0.44 mg per Kg) of methyl bis ( $\beta$ -chloroethyl) amine through technical error the only objective toxic effects of which were marked nausea and vomiting minimal diarrhea without occult blood in stools and profound leukopenia. Because of poor and transient therapeutic response she was placed on a pyridoxine free diet with added desoxypyridoxine at three hour intervals during the day totalling 25 mg per Kg daily. After a total of 1.5 Gm of desoxypyridoxine had been given she developed persistent nausea and suddenly lost consciousness became cyanotic and exhibited mass movements of extremities of a convulsive character. Following spontaneous

\* Generously supplied by Dr. D. F. Robertson, Merck Institute for Therapeutic Research.

recovery in about two minutes 100 mg of pyridoxine was given parenterally. The following day residual sequelae were noted in the form of diaphoresis, nausea and some amnesia for recent events, and the dose of desoxypyridoxine was lowered to 2.5 mg per Kg per day in three equal doses. During a fourteen day period on the deficient diet, weight loss, mental confusion and a 50 per cent reduction in lymph node size occurred. Repeated blood counts showed no abnormalities or changes, and a fasting blood sugar of 51 mg per cent did not differ significantly from the control value. On the hypothesis that additive effects might be obtained, a four day course of methyl bis ( $\beta$ -chloroethyl) amine was then given, totalling 0.4 mg per kg, there was further regression of adenopathy and some weight gain. The patient died suddenly within two weeks following hospital discharge at another institution. No necropsy was performed. The total duration of her illness had been nine months.

**Case 3 J S** This 52 year old white salesman entered the hospital with painless enlargement of the glands in his neck over a seven week period associated latterly with dysphagia, weakness and weight loss. Examination disclosed generalized lymphadenopathy particularly in the neck, hepatosplenomegaly and signs of fluid at the right lung base. Peripheral blood showed no anemia but a leukocytosis with a relative increase in lymphocytes some of which were immature forms. X rays of the chest revealed a right paratracheal shadow and confirmed the clinical impression of right pleural effusion. Biopsy of an axillary node disclosed *reticulum-cell lymphosarcoma*. Therapeutic response to a four day course of methyl bis ( $\beta$ -chloroethyl) amine totalling 0.4 mg per Kg was poor so that adenopathy remained stationary, right pleural fluid increased in amount and an exhausting nonproductive cough developed. Chest fluid revealed histologic changes compatible with lymphosarcoma at this time. The patient was then placed on a pyridoxine deficient diet with added desoxypyridoxine totalling 2.5 mg per Kg daily in three divided doses. During this period anorexia and cachexia became marked and he exhibited mental dullness, somnolence, increasing cough and edema of both legs and low grade afternoon fever. Some observers felt cervical lymph nodes became softer and smaller during this two weeks. The blood picture remained unchanged throughout and no xanthurenic acid excretion was detected in 24 hour urine specimens. Forty eight hours after resuming a regular diet the patient died suddenly. His illness had lasted about three months. Autopsy performed 100 hours postmortem showed gross evidence of widely disseminated invasive lymphosarcoma involving liver, spleen, heart, lungs, stomach and kidney as well as nodes in the mediastinum and abdomen. Microscopic examination confirmed these findings and in addition showed similar changes in prostate, bone marrow and thyroid gland. The nervous system appeared grossly and microscopically normal. Splenic sections were of interest in that scattered fields showed multinucleated lymphoid cells, fragmentation of nuclear material and minimal necrosis about lymphoid cell clusters. Dr. H. C. Stoerk who kindly reviewed these sections stated these latter sections bore some resemblance to changes seen in lymphoid tumors of pyridoxine deficient animals. However, in the main, comparison of the morphology of the tumor from autopsy material showed no significant variations from that seen in the pretreatment biopsy sections.

**Case 4 G deC** This 8½ year old white boy had a 3 week history of pharyngitis, cervical adenopathy and fever and showed hypertrophic gums, enlargement of the liver and all superficial nodes. Blood studies including sternal marrow aspiration were compatible with the diagnosis of *acute monocytic leukemia*. After fourteen days on a pyridoxine free diet with added vitamin antagonist, physical and hematologic findings remained unchanged. During the ensuing month his condition degenerated rapidly with continued fever, weight loss and hemorrhagic phenomena and he died at home in the ninth week of his illness.

**Case 5 C U** Blood studies confirmed the clinical impression of *acute lymphatic leukemia* in this 3 year old white male with symptoms of one month duration and fever, extensive purpura and marked hepatomegaly on physical examination. During 13 days of pyridoxine deficient diet with added antagonist the WBC dropped from 6100 to 1650, blast forms from 70 to 25 per cent and RBC from 2.39 to 1.54 millions with parallel hemoglobin changes. Ten days later the patient died in coma. No autopsy was performed. Total duration of his disease was two months.

**Case 6 J K** This 4 year old white male with symptoms of six weeks duration showed pallor, generalized adenopathy, hepatosplenomegaly and petechiae. Blood studies showed a high percentage of blasts and a diagnosis of *acute leukemia* was made. On the fifth day of a pyridoxine deficient diet with added desoxypyridoxine totalling 25 mg per kg he had two generalized convulsive seizures in rapid succession following which the desoxypyridoxine was reduced to 2.5 mg per kg. Because the child be-

came irrational for several hours twenty four hours later, the latter medication was discontinued, but the dietary regimen was prolonged until death eight days after its institution. During this period a marked and progressive leukocytosis with an increase in blasts from 90 to 100 per cent and a fall in RBC and Hgb values were noted. Death occurred at the end of this period in coma after an illness totalling two months duration. No autopsy was performed.

### DISCUSSION

In 2 of the 3 patients with lymphosarcoma there was evidence of moderate regression in the size of the lymph nodes. It is unwarranted to ascribe this change specifically to a pyridoxine deficiency, for Stoerk has shown that in rats exposed to adverse dietary conditions there is an approximately linear relationship between the body weight deficit and the thymic weight deficit.<sup>4</sup> On the reasonable assumptions that (a) an analogous situation pertains to man and (b) that the decrease in the weight of the thymus is an expression of generalized lymphoid atrophy, it is probable that the observed changes in the lymphadenopathy of our patients were coincident with the nonspecific malnutrition. This conclusion is further strengthened by the fact that there were no demonstrable morphologic evidences of specific cellular change attributable to pyridoxine deficiency in the tumor of the patient who came to necropsy.

The marked depression of hematopoietic function described in pyridoxine deficient experimental animals was not clearly demonstrated in the patients of this study. Admittedly it is difficult to assess this particular point in patients with acute leukemia and widely disseminated lymphosarcoma. Since all of the cases had anemia of varying degrees of severity at the onset of the dietary regimen, it was impossible to determine the effect of the diet and desoxypyridoxine on erythropoiesis. It is to be noted, however, that leukopenia, lymphocytopenia, and thrombocytopenia did not occur during the period of observation except in one case of acute leukemia. In this patient there was no significant alteration of the hemogram and the development of leukopenia is entirely compatible with the natural course of the disease.

The two episodes of central nervous system excitation seen in our patients were probably an expression of acute pyridoxine deficiency induced by the large doses of the pyridoxine antagonist, desoxypyridoxine. Mushett et al.<sup>11</sup> have reported convulsions in experimental animals given large doses of desoxypyridoxine, and Wintrobe and his associates have described convulsive seizures in pyridoxine deficient swine which closely resemble grand mal epilepsy.<sup>12</sup> The signs and symptoms seen in our patients were also similar to this cerebral dysrhythmia.

Kynurenine and xanthurenic acid are abnormal metabolites of tryptophan which are excreted in the urine of animals which are deficient in pyridoxine.<sup>8-13</sup> Xanthurenic acid excretion in man has not been noted<sup>10</sup> and this has suggested that tryptophan degradation varies in different species. To our knowledge, such a rigorous pyridoxine deficient diet has not previously been employed in the studies of xanthurenic acid excretion in humans. Inasmuch as 2 of the patients failed to excrete xanthurenic acid while on the diet and while receiving desoxy pyridoxine, additional circumstantial evidence is provided that tryptophan is not metabolized

in the same way in all species, however, the possibility that the patients were not deficient in pyridoxine cannot be excluded

The criteria of a pyridoxine deficiency in experimental animals include depression of hemopoiesis, atrophy of lymphoid tissue, demyelinating lesions of the central and peripheral nervous system, and disturbance of tryptophane metabolism. Applying these criteria to the patients reported here would lead to the conclusion that (a) either a pyridoxine deficiency had not been induced or (b) pyridoxine is not essential in human nutrition. A final possibility is that the manifestations of vitamin B<sub>6</sub> deficiency in man are entirely different from those observed in animals and that they were unrecognized in the patients of this study. It is impossible to state with assurance which of the above possibilities pertained in these experiments. In mice, Stoerk has observed lymphoid regression within five days after the onset of desoxypyridoxine and a pyridoxine restricted diet.<sup>12</sup> This would indicate that there are not large stores of the vitamin in the body. Wintrobe and his associates, on the other hand, noted that in swine on a pyridoxine deficient diet two to seven weeks passed before there were unmistakable signs of the specific vitamin deficiency.<sup>13</sup> Since there was clear evidence of nonspecific malnutrition in our patients within fourteen days, a more protracted period of dietary experimentation was not justifiable.

It may be stated unequivocally that, under the conditions of the experiment, there was no evidence that restriction of the pyridoxine intake together with desoxypyridoxine had any therapeutic value. In the 3 patients with lymphosarcoma, a course of nitrogen mustard (methyl bis (beta chloroethyl) amine) was given following the completion of the experimental dietary period to determine whether a greater response would be produced by the chemotherapeutic agent. There was no significantly greater regression of the tumor masses observed following the post-pyridoxine deficiency nitrogen mustard therapy than had occurred with previous chemotherapy.

#### SUMMARY AND CONCLUSIONS

Three patients with disseminated lymphosarcoma and 3 cases of acute leukemia were placed on a pyridoxine deficient diet together with desoxypyridoxine for periods of four to fourteen days. Although there was evidence of malnutrition in the form of weight loss and weakness, none of the signs of specific pyridoxine deficiency described in animals was observed in the human. There was no unequivocal evidence of depression of hemopoiesis, no significant atrophy of lymphoid tissue, no signs of demyelination of nerves, and no abnormality of tryptophane metabolism determined by urinary xanthurenic acid excretion. The possibility that the dietary restriction of pyridoxine was too brief for the development of a deficiency syndrome was considered, but it was pointed out that the rigors of the procedure were too great to justify more protracted periods of observation.

Two patients had acute toxic manifestations following the administration of large doses of desoxypyridoxine. These were characterized by transient epileptiform convulsions. There were no sequelae and no recurrence of the symptoms when the dose of the drug was reduced.

There was no evidence that the restriction of pyridoxine in the diet together with desoxy pyridoxine for periods up to two weeks had any therapeutic effect in lymphosarcoma or acute leukemia. Also, no potentiation of the cytotoxic effect of nitrogen mustard was observed in the patients with lymphosarcoma when chemotherapy was given after the completion of the pyridoxine deficient regimen. It is to be emphasized that this does not absolutely exclude the possibility that pyridoxine deficiency may adversely affect lymphosarcoma in man. The short duration of the experiment and the well known refractoriness to any form of therapy of the tumors in these patients are factors which may have militated against a satisfactory outcome of the regimen.

## A RAPID DIAGNOSTIC TEST FOR SICKLE CELL ANEMIA

By HARVEY A. ITANO, M.D., AND LINUS PAULING, Ph.D.

**S**ICKLE cell anemia is a congenital chronic hemolytic type of anemia characterized hematologically by the development of oat-shaped and sickle-shaped erythrocytes. Other cellular abnormalities which are due to excessive blood destruction and active blood formation are also seen in blood smears. Six to 10 per cent of Negroes possess the sickle trait<sup>2, 3</sup>, their red blood cells have the capacity to sickle, but most of these individuals do not develop anemia.

The course of the sickling process as observed under the microscope has been described in detail by several investigators,<sup>4, 5, 6, 10</sup> but little is known about the physical processes involved in sickling. It has been established, however, that the erythrocytes of individuals with sickle cell anemia and sickle cell trait become sickled when the hemoglobin is reduced.<sup>8, 14</sup> When the hemoglobin is combined with oxygen or carbon monoxide, the cells are indistinguishable in form from normal erythrocytes. The term promeniscocyte has been applied to the latter form and meniscocyte to the former.<sup>11</sup> Hahn and Gillespie<sup>8</sup> and Sherman<sup>14</sup> obtained sickling physically by reducing the partial pressure of oxygen over suspensions of promeniscocytes. They were able to reverse the process by passing oxygen or carbon monoxide over meniscocytes. When oxygen is removed from promeniscocytes, their hemoglobin aggregates in one or more foci within the cells, and the cell membrane collapses. When oxygen is added to these cells, they resume their normal contour, and hemoglobin appears to be distributed uniformly throughout their interior. Meniscocytes are strongly birefringent under the polarizing microscope<sup>14</sup> while promeniscocytes are not.

When a drop of blood is sealed between a cover slip and a slide, the decline in oxygen tension due to oxidative processes in the blood cells leads to sickling.<sup>7</sup> This is the common diagnostic test for sickle cell anemia and sickle cell trait used in clinical laboratories. Sherman found that increase in temperature, high leukocyte count, and bacterial contamination, all of which increase the rate of oxygen consumption, accelerated the sickling process. In another method, a saline citrate suspension of blood is allowed to stand in a test tube under a layer of paraffin oil until sickling takes place.<sup>1</sup> In employing any of the common diagnostic tests for sickling it is desirable to obtain blood which has a low fraction of oxyhemoglobin. Thus, the moist stasis method,<sup>13</sup> in which blood is obtained from a patient's finger after its circulation has been occluded for five minutes, gives the most rapid and consistent results. Even with this method it is sometimes necessary to observe the preparation for several hours before the result is conclusive.<sup>8</sup>

In order to find a more convenient and rapid method of producing meniscocytes

Contribution No. 1186 from the Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, Calif.

This work was done under a grant from the U. S. Public Health Service and was briefly reported by Dr. Dan H. Campbell at the Hematology Symposium of the U. S. Public Health Service held at St. Louis, Mo., on February 2, 1948.

we turned to chemical reducing agents. Sodium dithionite,  $\text{Na}_2\text{S}_2\text{O}_4$ , rapidly reduces oxyhemoglobin to reduced hemoglobin, and this property suggested its use in testing erythrocytes for sickling. When a solution of sodium dithionite was added to promesococytes, nearly all of the cells showed sickling or the early changes in the sickling process within a few seconds. Dithionite ion tends to decompose to thiosulfate and sulfite with formation of hydrogen ion<sup>9</sup> so that solutions made up from commercial preparations of sodium dithionite are often strongly acid in reaction, but by adding  $\text{Na}_2\text{HPO}_4$  to the solutions it is possible to increase the pH and at the same time provide a buffering medium. Hahn and Gillespie found that sickling was obtained most consistently if cell suspensions were buffered at a slightly acid pH. We have prepared a satisfactory reagent by adding 0.114 M aqueous  $\text{Na}_2\text{HPO}_4$  to 0.114 M aqueous  $\text{Na}_2\text{S}_2\text{O}_4$  until the final pH was 6.8. The ratio of the volumes of  $\text{Na}_2\text{HPO}_4$  and  $\text{Na}_2\text{S}_2\text{O}_4$  necessary to obtain this pH was about three to two.

The blood used in the following experiments was obtained from 6 different cases of sickle cell anemia, 3 of whom were being treated for exacerbations and 3 of whom were in remission. An excess of the dithionite reagent was added to promesococytes on a microscope slide, almost immediately changes were evident in the erythrocytes. Typical crescentic forms did not appear in large numbers, presumably because of the time required for the reduced hemoglobin molecules to become oriented in what Ponder calls the paracrystalline state.<sup>11</sup> However, nearly all of the cells underwent changes in contour, and other changes described by earlier observers took place at an accelerated rate. The forms of many of these cells corresponded to the holly wreath cells of Sherman and cells classified as "abnormal" by Reinhard and his co-workers.<sup>12</sup> After about fifteen to thirty minutes the aggregates of hemoglobin in many of the cells became birefringent. The presence of so many holly wreath cells is in accord with Sherman's observation that this form appears in large numbers when the rate of removal of oxygen is rapid. Since dithionite does not react with carbon monoxide, promesococytes saturated with carbon monoxide would not be expected to undergo changes in contour upon addition of this reducing agent. This is indeed the case. Although no sickle cell trait blood was available to us for study, there is good reason to believe that such blood would behave in the same manner as sickle cell anemia blood.\*

#### METHOD

The rapidity and simplicity of this test suggests that it would be useful as a clinical laboratory procedure for diagnosing sickle cell anemia and sickle cell trait. No special precautions are necessary in collecting the blood for this test; oxygenated cells may be used since an excess of reducing agent can always be added. The test works equally well with oxalated blood or fingertip puncture specimens and may be applied in several ways. (1) About 0.05 ml. of reagent may be added to a very small drop (about 0.01 ml.) of blood on a slide. A cover slip is then laid over

\* A brief note by da Silva (Science 107: 221 (1948)) which appeared since the preparation of this paper indicates that he has successfully identified sickle cell trait by a procedure similar to method (1) below.

the mixture and cells observed under a microscope (2) An excess of reagent may be added to a small volume of blood in a test tube and a drop of the mixture observed (3) A convenient method for studying the entire process of sickling in a short period of time involves the use of a hemocytometer counting chamber The chamber is half filled with a dilute saline suspension of promiscocytes, the reagent is then added to fill the rest of the chamber The erythrocytes may be observed as the reducing agent diffuses into the part of the chamber which they occupy

Since the dithionite reagent is unstable as mentioned above, its reducing power should be tested frequently by the addition of a test portion to a dilute suspension of oxygenated erythrocytes If the reagent is satisfactory, a change from the color of oxyhemoglobin to that of reduced hemoglobin should be observed A large volume of stock  $\text{Na}_2\text{HPO}_4$  solution may be prepared, but it is desirable to make up the  $\text{Na}_2\text{S}_2\text{O}_4$  solution daily

#### ACKNOWLEDGMENTS

We are indebted to Dr Edward K Evans and D Travis Winsor for their aid in obtaining the blood used in these experiments

# THE MECHANISM OF PETECHIAL HEMORRHAGE FORMATION

By J G HUMBLE, M R C S , L R C P

THE OCCURRENCE of petechial hemorrhages in the skin and mucous membranes is a well known sign in many hemorrhagic diseases and in other complaints. Little is known, however, of the mechanism by which they are produced or the exact segment of the vessel or vessels at fault. Histologic preparations show merely an exudation of red cells, sometimes of polymorphonuclear neutrophil leukocytes around the minute vessels in the dermis, the vessel walls themselves usually appearing intact. In the present investigations the formation of petechiae by the tourniquet test (capillary resistance test) in the skin of patients suffering from various hemorrhagic diseases has been studied by capillary microscopy.

## METHOD AND APPARATUS

The patients lay comfortably in bed, the arm extended at right angles to the trunk, in the position of full supination resting on a firm table. The cuff of a blood pressure apparatus was adjusted to the upper arm and the skin in the antecubital fossa was shaved to remove hair and superficial squama. The area chosen was then covered with cedar wood oil. A Leitz Ultra-Pak microscope was used to study the skin vessels ( $11\times$  objective with the dipping cone attached and a  $10\times$  ocular). By adjustment it is possible to obtain optical continuity from the oil to the lens system to avoid surface glare from the oiled skin. A clear view of the blood in the minute skin vessels is thus obtained at a magnification of  $110\times$ . The vessels that are seen with the cuff uninflated are few and far between and are the terminal capillary loops. They are usually found in clusters of three or four. The cuff is then gently inflated to a pressure of 90-100 mm. of mercury (or between the systolic and diastolic blood pressure). As the venous system of the skin fills with blood it is possible to see the previously invisible superficial plexus of minute venules and the connections of the end capillary loops to this plexus. In the creases of the elbow it is also possible to see the end of the precapillary arteriole by the blood spurting into view as the capillary loop from the depths of the skin (fig. 1). It is at this point that petechial hemorrhages form, irrespective of the type of disease studied. The behavior of the exuded blood and the shape and character of the lesion formed is, however, different in the various types of disease studied. The following cases have been thus studied.

- (1) Essential Thrombocytopenic Purpura—5 cases  
Thrombocytopenic purpura secondary to
  - (a) Sedormid intoxication—1 case
  - (b) Gold intoxication—1 case
  - (c) Novarsenobenzol intoxication—1 case

## (II) Combined Form of Purpura

Aplastic anemia thrombocytopenia and hypoprothrombinemia

(a) Idiopathic form—1 case

(b) Novarsenobenzol intoxication—1 case

FIG. 1 Simplified section of skin to show the nature and position of the terminal vessels. The dotted line indicates the position at which the petechiae form. Only the vessels in solid black can be seen by the microscope (1) horny layer of skin, (2) malpighian layer, (3) level of petechial hemorrhage formation, (4) 1st collecting venule (5) terminal arteriole

## (III) Non Thrombocytopenic Purpura

(a) Anaphylactoid purpura—2 cases

(b) Essential hypoprothrombinemia—1 case

(c) Potassium iodide sensitivity—1 case

(d) Scurvy—1 case

(e) Malignant hypertension—1 case

The hematologic features of the cases are summarized in table 1

In essential thrombocytopenic purpura the exudation of blood occurs at first as a shower of red cells, which can be seen to be hurled from the vessels, and which travel at least three times the diameter of the vessel before they are brought to rest

There is no breach of the blood stream in the capillary, nor is it obliterated by pressure of the effused blood. The segment of vessel through which the red cells pass is very small in length, and the exuded cells form a thin disc, which later extends superficially to form a conical lesion around the arteriolar end of the capillary. The effused red cells are taken up by the skin lymphatics only very slowly (fig 2, 1-4).

*Secondary thrombocytopenic purpura* In the Sedormid and Gold and N A B intoxication cases studied, the lesions formed quickly and there was evidence that the red cells were rapidly taken up by lymphatics, as fine columns of red cells formed from the edges of the disc and rapidly extended.

*Monocytic leukemia* In this case the blood left the vessel very rapidly indeed, and length of affected vessel was greater, for the effused blood formed a much thicker disc. It was rapidly, almost immediately, taken into the lymphatics.

*Anaphylactoid purpura* In the two cases studied exudation was much more diffuse and there was considerable effusion of fluid as judged by the rapidity in which the details became obscured by edema. Lymphatic absorption is immediate. The iodide intoxication gave a similar picture.

*Essential hypoprothrombinemia* This case was characterized by the curious way the effused blood tracked superficially around the capillary loop, with very little lateral extension of the lesion. Lymphatic absorption was very slow.

*Aplastic anemia* Both cases reacted similarly. Two forms of lesion were produced, a large, rapidly forming hemorrhage which formed so rapidly that detailed observation was not possible, and a smaller lesion which resembled those seen in essential thrombocytopenia. Lymphatic absorption was very slow.

*Scurvy* The petechiae which formed were of two types, (a) large (up to 2 mm in diameter) and (b) small in size. The small lesions formed in the usual way from the arteriolar end of a single capillary loop, the large lesions formed similarly from a cluster of adjacent capillary loops, usually three in number, apparently arising from a common arteriolar twig. These lesions rapidly became confluent and the combined lesion spread rapidly. The effused blood was quickly taken up by the lymphatics.

*Malignant hypertension* The lesions here did not appear until the constricted capillary loops were fully dilated. The lesions spread rapidly and tended to be confluent (fig 3). Absorption was moderately rapid.

#### COMMENT

It will be noted that despite the different causes for the purpuric manifestations, the lesions produced all lay in the same segment of vessel, the arteriolar end of the capillary loop. In no case were lesions found elsewhere.

It would seem under the conditions of this test that this small segment of the vessel is unable to prevent the escape of red cells from the lumen. It has been shown by McFarlane<sup>2</sup> that the nailfold capillaries in various kinds of purpura display abnormal reactions to puncture with a quartz fibre, in that the capillary loop is unable to contract as do normal capillaries under similar stimuli. The part of the capillary from which the red cell exudation occurs is, moreover, that part

TABLE 1—Hematological Features of 17 Cases of Hemorrhagic Disease

No	Diagnosis	Age and sex	Duration of symptoms	Nature of lesions	Bleeding Time	Coagulation time	Platelet count per cu mm	Prothrombin index %	Treatment and sequel

FIG 2. Simplified drawing of the terminal vessels as seen through the microscope to illustrate the formation of a petechial haemorrhage in essential thrombocytopenia purpura

FIG 3. Photomicrograph of lesion from case 16 (a) small early petechial hemorrhage (b) larger lesion (c) dilated capillary loops (d) relatively constricted loop

from which fluid leaves the vessels for the tissues normally Landis' showed by direct measurement that the intracapillary pressure at this point is higher than

elsewhere in the loop. Furthermore, the lesions occur at a point where the tightly constricted precapillary arteriole dilates suddenly to form the capillary loop. It is evident that this arteriolar-capillary junction is of great importance in the maintenance of blood flow and the nutrition of tissues generally. It is tempting to postulate that a selective poisoning of this junction could produce hemorrhages in the mucosae and also cause thrombocytopenia by an upset of megakaryocyte nutrition. The poison must leave the circulation for the tissues at the point described, and the cells of the vessel wall must be thus exposed to a much greater selective concentration than elsewhere. This theory can be applied to essential thrombocytopenic purpura on the assumption that the spleen produces a toxic substance. It explains the prompt cessation of hemorrhage immediately following splenectomy in this disease. Similar explanations can be deduced to fit other hemorrhagic syndromes and diseases.

#### SUMMARY AND CONCLUSIONS

- 1 The capillary resistance test has been studied by a special technic of capillary microscopy
- 2 Seventeen cases of hemorrhagic diseases of differing etiology have been thus studied
- 3 The site of capillary hemorrhage has been localized to the arteriolar end of the capillary loop
- 4 Selective damage to the arteriolar-capillary junction will explain many types of hemorrhagic syndromes

#### ACKNOWLEDGMENT

I wish to thank the honorary staff of the Westminster Hospital for permission to study cases under their care. I am much indebted to Dr P. Hansell and Miss F. E. McAdoo of the Westminster Hospital Department of Medical Photography for assistance with the illustrations.

## EDITORIAL

AND NOW B<sub>12</sub>

IN THESE crowded days when one therapeutic miracle succeeds another in rapid succession, the appearance of a new substance with almost incredible therapeutic effects inspires but little excitement. Successive triumphs by teams of chemists, often working in commercial laboratories, appear to have left us jaded. The isolation of vitamin B<sub>12</sub> in the research laboratories of Merck and Company in this country<sup>1</sup> and almost simultaneously in the Glaxo Laboratories in England<sup>2</sup> is the most recent case in point. Here is a substance that, when given to a patient suffering from pernicious anemia, results in a maximal reticulocyte response and a near maximal erythrocyte response following a single injection of 5 to 10 thousandths of a milligram (0.00005 Gm.)<sup>3</sup> Has there ever been in the history of medicine a more potent material, microgram for microgram?

Folic acid (pteroylglutamic acid) came out of the research laboratories of the Lederle Laboratories. Its history has been told in these columns.<sup>4</sup> Folic acid and the folic acid antagonists<sup>5</sup> will long stand as a monument to Dr. Yellapragada SubbaRow, who initiated work with these materials and carried it along brilliantly.

It is of interest that a bacterium was used as the assay animal in testing both these materials. With folic acid, *Lactobacillus casei* was used, with vitamin B<sub>12</sub>, it was the *L. lactis* Dorner.<sup>6</sup> Successive assays of concentrated and reconcentrated material required a readily available means for assay and this the bacterium supplied, since the necessary growth factor proved to be identical with the liver extract factor required by the human in erythropoiesis.<sup>6</sup>

Search for the factor in liver extract that is responsible for its hematopoietic and neurologic effects has proceeded almost continuously since liver was first found to be effective in the treatment of pernicious anemia. A year after the introduction of liver, Cohn<sup>7</sup> in 1927 produced a liver extract called Fraction G, this was a water soluble material obtained after protein precipitation. From this substance a solution was later prepared for parenteral use, at first in crude form containing only 1 or 2 units per cc. of extract, and later in concentrated form containing 10-15 units per cc. The concentrated extracts proved to be of greatest value since in a small amount of solution they gave maximal effects with the least local irritation. They were furthermore highly potent in combating and preventing neurologic involvement.

The place of the crude liver extracts in therapy became quite limited, particularly with the advent of folic acid. This latter material, although only partially helpful in typical Addisonian pernicious anemia was of distinct value in other (atypical) members of the pernicious anemia family, i.e., in sprue, tropical macrocytic anemia, pernicious anemia of pregnancy and megaloblastic anemia of infancy.<sup>8</sup> Here the response was often better than with liver extract and neurologic involvement did not occur.

The mysterious relationships between folic acid and liver extract, which are as yet by no means solved, will probably become better understood now that chemi-

cally pure vitamin B<sub>12</sub> is at hand. At this writing, B<sub>12</sub> appears to be the long-awaited liver extract factor. In minute amounts it appears to possess all the effects of liver extract, both hematologically and neurologically. That it acts on the neurologic disturbance would tend to discredit the assumption that the hematologic and the neurologic lesions of pernicious anemia are due to separate deficiencies.

Some of the macrocytic deficiency states may conceivably not be benefited by B<sub>12</sub> administration. This may indicate that the pernicious anemia family of diseases is composed of a group of different types of deficiency states but characterized by the common denominator of a megaloblastic bone marrow and macrocytic anemia. In one group are those cases primarily benefited by liver extract, the other is composed of cases in which the best effects appear to be obtained with folic acid. It is reasonable to assume that in the latter group the primary deficiency is in folic acid. A working concept for the present (subject to change at a moment's notice) is as follows:

<i>Pernicious Anemia Family (Megaloblastic Bone Marrow with Macrocytic Anemia)</i>	
<i>Deficiency in Vitamin B<sub>12</sub></i>	<i>Deficiency in Folic Acid</i>
Addisonian Pernicious Anemia	Sprue (certain cases)
	Tropical Macrocytic Anemia
	Refractory Megaloblastic Anemia
	Pernicious Anemia of Pregnancy
	Megaloblastic Anemia of Infancy
Sprue (certain cases)	

It should be noted that the syndromes in which folic acid is most effective include largely those conditions in which free hydrochloric acid is present in the gastric juice. In the presence of complete achlorhydria, as Spies<sup>8</sup> has already postulated, folic acid does not protect against neurologic involvement. Already, there is indication that B<sub>12</sub>, like liver extract, may be ineffective in the pernicious anemia of pregnancy, whereas folic acid is highly effective.<sup>9</sup> Further investigations will undoubtedly bring a more complete elucidation of the different types of deficiency states with macrocytic anemia.

Although the chemical formula of vitamin B<sub>12</sub> has not as yet been announced, it may be presumed that work on this problem as well as on methods for synthesis is going on. In solution, B<sub>12</sub> has a purplish hue and the startling discovery has been made by both the Glaxo and Merck Laboratories that this is due to the presence of cobalt.<sup>10</sup> For years, cobalt has been used in the experimental production of polycythemia.<sup>11</sup> The epizootic occurrence of cobalt deficiency in sheep and cattle in Australia, New Zealand, Canada, and even in this country has been reported.<sup>11</sup> Animals so affected have developed anemia, changes in coat, weakness, emaciation, and finally death as the result of the cobalt deficiency. The whole subject of cobalt metabolism and of the activities of this trace element in the human economy is thus thrown wide-open for new vistas of research.

Vitamin B<sub>12</sub> may prove to play a prominent role not only in therapeutics but also in the field of animal nutrition. It has been recognized for a considerable period that an unknown substance or substances present in crude materials such as fish meal, cow manure and liver is required for optimum growth of chicks and for

adequate hatchability of hen's eggs.<sup>10</sup> Recently, the administration of a concentrate of this animal protein factor prepared by Stokstad et al.<sup>11</sup> in two cases of pernicious anemia produced a well defined hematopoietic response. More recently, Ott and collaborators<sup>12</sup> demonstrated that crystalline vitamin B<sub>12</sub> can replace these crude sources of the animal protein factor in promoting chick growth. Thus, B<sub>12</sub> may be responsible either wholly or in part for the growth promoting activity of such feed supplements.

The finding of a potent growth factor in cow manure and doubtless in the excreta of other animals harks back to the days of the witches' brew, and to the naive medicine of certain country districts. Perhaps there was something in these old concepts of medical therapy after all!

In this complex modern world where chemists and physicists and mathematicians are constantly at work, one never knows what new complexities lie ahead of us, what new worlds await us in tomorrow's news!

WILLIAM DAMESHEK, M.D.

## CYTOLOGY

STUDIES ON THE MEGAKARYOCYTE I THE NORMAL GRANULOPOIESIS OF THE MEGAKARYOCYTE II DEFICIENT GRANULOPOIESIS IN THE MEGAKARYOCYTE IN ESSENTIAL THROMBOCYTOPENIC PURPURA *E. Schwarz* From Department of Hematologic Research, Michael Reese Hospital, Chicago, Ill. Arch. Path. 45: 333-353, 1948

This series has as background Schwarz's experience since 1888, when he published his first paper and his chief preoccupation was with morphology and biology, to his recent freedom from clinical and teaching duties and a return to studies in cytology. His contribution to the megakaryocyte problem is chiefly a focusing of attention to the previously neglected developmental history of the granulation and the light areas in the cytoplasm. After becoming thoroughly acquainted with the appearance of early developmental forms of normal megakaryocytes, his studies were carried over to cases of Werlhof's essential thrombocytopenic purpura. In megakaryoblasts and early promegakaryocytes the first evidence of granulopoiesis appears in a light staining area located close to the nucleus. Because this area increases and becomes pinkish with the growth and development of the cell, Schwarz has designated it the "functional area." In the light of some recent studies on the cytoplasm of immature blood cells, the proposed term is particularly satisfactory because it probably represents the negative images of underlying cytoplasmic organoids and as such justifies the importance which Schwarz has assigned to it. Under normal conditions, the functional area is related to granulopoiesis. But under pathologic conditions, as in some cases of essential thrombocytopenic purpura, the functional area does not produce azurophilic granules and it may even become hyalinized. According to Schwarz's analysis of megakaryocytes in essential thrombocytopenic purpura, these cases fall into three groups: those with intact granulopoiesis, which are the common type; those with functional disturbance of granulopoiesis, and those with degeneration and destruction of megakaryocytes. The type with hyalinization of the functional area may be due to deficiency of some substance necessary for megakaryocytic granulopoiesis. It is to be regretted that this important article was not illustrated with colored plates.

O P J

CONTRIBUTION TO THE PATHOLOGY OF THROMBOCYTOGENESIS *F. Hefmanský* From the Department of Medicine, Hospital of Charitable Sisters, Prague. Čas. lek. čes. 86: 232, 1947

In accordance with Jasínský (Schw. med. Wschr. 12:18, 1944) the megakaryocytes were classified into six groups, namely megakaryoblasts, promegakaryocytes, basophilic megakaryocytes, transitional forms, granular megakaryocytes and nude nuclei.

In five cases of thrombocytopenia the megakaryocytic formula was the following:

CASE 1. Myelophthisic anemia due to radium with leukopenia and thrombocytopenia. FORMULA

0-1-3-15-77-4

CASE 2. Acute thrombocytopenic purpura. FORMULA 2-12-13-24-48-0

CASE 3. Recurrent essential thrombocytopenia. FORMULA 1-3-7-16-72-1

CASE 4. Essential thrombocytopenia. FORMULA 0-2-5-8-79-6

CASE 5. Hypersplenic thrombocytopenia in splenomegalic cirrhosis. FORMULA 1-4-5-6-81-3

No relation could be found between the intensity of the morbid state, the appearance and num

platelets and the distribution formula of megakaryocytes in the bone marrow, nor was hypersegmentation or vacuolization of megakaryocytes in any way connected with the specific thrombocytopenic syndrome. In many cases of disturbed thrombocytopoiesis no changes at all could be observed in the megakaryocytes in the bone-marrow.

**INDIVIDUAL CELLS UNDER PHASE MICROSCOPY BEFORE AND AFTER FIXATION** R. Buchsbaum. From Institute of Radiobiology and Biophysics, The University of Chicago. Chicago, Illinois. *Anat. Rec.* 122: 19-36, 1948.

The use of phase microscopy makes possible a method by which the cytology of living and dying cells can be studied without the interference of fixatives. Zollinger has recently reported changes observed of tumor cells *in vivo* and *in vitro* with the phase microscope (*Am. J. Path.*). Buchsbaum has utilized a similar approach to determine which fixatives yield preparations most representative of the living cell. His studies were limited to salamander macrophages grown in tissue cultures. Certain fixatives like absolute alcohol, Carnoy's and Bouin's solutions distort the cytoplasm more than the nucleus. Formol alone in alkaline solution was a better fixative than either of these and better than formol in acid solution. The best general fixatives were Zenker formol and Zenker formol-osmic, the latter being the better of the two. Although phase microscopy alone has not revealed any new structure which had not been preserved by the better fixatives, it does offer a means of checking the rationale for using them.

O.P.J.

**LOCALIZATION OF LIPIDS AND OTHER CHEMICAL SUBSTANCES IN THE MAST CELLS OF MAN AND LABORATORY MAMMALS** W. Montagna and C. R. Noback. From Department of Anatomy, Long Island College of Medicine, N. Y. *Anat. Rec.* 100: 535-546, 1948.

Because there is convincing evidence that tissue mast cell granules contain heparin, quite a few articles have been published recently dealing with observations on the chemical cytology of these cells. The present article extends this knowledge by demonstrating that mast cell granules contain phospholipin, peroxidase and lipase.

O.P.J.

**ASPIRATION OF BONE MARROW FROM THE ILIAC CREST: COMPARISON OF ILIAC CREST AND STERNAL BONE MARROW STUDIES** M. A. Rubinstein. From the Montefiore Hospital, New York. N. Y. *J. A. M. A.* 137: 1281-1285, 1948.

The author of this article has performed over 1000 aspirations of the iliac crest bone marrow, and presents his findings and technique with the thesis that marrow puncture, when indicated, can be performed easily, safely, and advantageously at the iliac rather than the sternal region. In 216 of the 1000 patients comparative studies were done on samples of marrow obtained simultaneously from the two sites; the normal marrow picture was identical at both locations and when the marrow was abnormal the pathologic alterations usually occurred in parallel fashion in both areas.

The advantages of the iliac crest over the sternum, according to the author, include (1) safety, since no vital organs underlie the ilium; (2) ease of performance, by virtue of less pain and less apprehension than at the sternum; and (3) ease of repetition.

Of especial interest were those diseases of the marrow in which there was patchy involvement of the bone: certain leukemias, osteosclerosis, myeloma, neoplastic infiltration. In several such cases diagnosis was made by iliac aspiration after a sternal puncture was fruitless. (In others the reverse was true.) The iliac bone bears no special virtue in such cases, presumably, in such diseases marrow aspiration at various portions of the sternum and at the spinous processes—as well as at the iliac crests—may be required to obtain diagnostic information. The statement, therefore, that in a number of cases of malignant infiltration of the bone marrow neoplastic cells were seen more often in the iliac than in the sternal aspiration is somewhat startling and will bear substantiation.

The ilium, spinous processes, and sternum are now commonly used sites for puncture aspiration of the bone marrow. In selected cases multiple punctures in these sites may prove of value over single punctures at any one site. (See Loge, *Blood* 3: 198, 1948, and Dameshek, *Blood* 3: 209, 1948).

## ERYTHROCYTES AND ERYTHROCYTIC DISEASE

CHRONIC HAEMOLYTIC ANEMIA WITH HAEMOGLOBINURIA THE MARCHIAFAVA MICHELI & SYNDROME M D Hickey and L. K. Malley From the Mater Misericordiae Hospital, Dublin Quart J Med 17 1 1948

The 49 year old man whose case history is reported in this paper showed nocturnal hemoglobinuria for a period of ten days beginning twenty four days after multiple transfusions. He exhibited persistent hemoglobinuria without diurnal variation during the oral administration of iron but at other times he was free of hemoglobinuria.

Serum heated to 56 C. was shown to have an inhibitory effect on hemolysis of the patient's cells in vitro, and the intravenous administration of 400 cc. of heated serum was followed by a cessation of hemoglobinuria for thirty-six hours.

The number of cells susceptible to acid hemolysis was computed and correlated with the effect of transfusion and the reappearance and cessation of hemoglobinuria. However, judging from the data presented it is evident that the occurrence of hemoglobinuria is influenced by some factor in addition to the number of susceptible cells present.

R.S.E.

TRUE PERNICIOUS ANEMIA WITHOUT ACHLORHYDRIA Alex Murphy M J Australia 1 521, 1948

The finding of free hydrochloric acid in the gastric secretion of a 23 year old girl who appeared to have typical Addisonian pernicious anemia led the author to attempt to satisfy all criteria as to diagnosis and to exclude other types of macrocytic anemia. The subject appeared to have pernicious anemia because of a typical reticulocyte response to refined liver extract followed by a rise in the erythrocyte count and hemoglobin. The only atypical finding was an MCHC of 27.6 per cent which is not explained. Later, a relapse was induced by withdrawing liver which resulted in reappearance of anemia and macrocytes. Biologic assay demonstrated a lack of extrinsic factor in the gastric contents. The failure to find megaloblastic change in the marrow makes the case not quite complete but is readily explained since marrow examination was not made until seventeen days after treatment. Megaloblastic changes did not occur during the partial relapse. The author believes that it is possible to conclude that true pernicious anemia can and does occur in persons with free hydrochloric acid in their gastric juice and therefore that achlorhydria is not essential to the development of true pernicious anemia.

R.S.E.

ANOMALIES OF THE INTESTINAL ABSORPTION OF FAT II THE HAEMATOLOGY OF IDIOPATHIC STEATORRHEA W T Cooke, A C Frazer, A L P Peeney H G Sammons and M D Thompson From the Queen Elizabeth Hospital and the Department of Medicine and Pharmacology Birmingham University Quart J Med 18 9-23 1948

Studies of the peripheral blood particularly the red cell morphology of idiopathic steatorrhea are reported. The most consistent abnormalities were the increase in mean cell diameter, an increase in the diameter thickness ratio and an increase in resistance to hemolysis in hypotonic saline. The mean corpuscular hemoglobin concentration was below normal in most instances. In 4 of 17 cases studied the sternal marrow was indistinguishable from that of pernicious anemia. In the remaining 13 the sternal marrow showed a mixture of iron deficiency normoblasts and large atypical normoblasts. Fecal urobilinogen was increased in 5 of 11 patients studied. There was no consistent response to therapy with refined and crude liver B complex iron and a variety of other agents. The authors discount the similarity of the anemia of idiopathic steatorrhea to pernicious anemia and the unitarian theory of the etiology of macrocytic anemias in general, a concept which in its strict interpretation has already been challenged by the discovery of the Wills factor.

The authors conclude that the similarity of the anemia of idiopathic steatorrhea to pernicious anemia is largely superficial.

R.S.E.

THE NORMAL RED CELL IN INFANCY AND CHILDHOOD SOME RECENT ADVANCES B Dittus and I J Wolman From The Children's Hospital of Philadelphia (Department of Pediatrics School of Medicine University of Pennsylvania) Am J M Sc. 215 694-709 1945

This article discusses in a general way the structure of the red cell and hemolytic mechanisms with special reference to osmotic resistance. Fetal erythropoiesis and normal red cell values in infancy and childhood are also reviewed. References are well chosen and bring the subjects dealt with up to date relating to pediatric hematology.

C.A.F.

OBSERVATIONS ON ANEMIAS IN STARVATION O. Seyka From the District Hospital L 124 in Terežín ghetto Čas lékař čes 86 583, 1947

These observations were made on prisoners in concentration camps in Terežín Bohemia. Under extremely difficult conditions, the author succeeded in performing blood examinations in 50 healthy male prisoners, the red blood cells were almost normal in number but they were distinctly macrocytic with color index of 1.2 to 1.3. These blood examinations were supervised by Professor Hirschfeld who himself, was one of the prisoners. This macrocytosis seems to have been conditioned by a deficiency in amino acids and vitamins, but no definite conclusions could be reached in view of the impossibility of exact scientific investigation.

M.N.

RETICULOCYTES EXAMINED BY THE DARKFIELD METHOD F. Lebert From the 3rd Medical Clinic, Charles University Prague Čas lékař čes 86 11, 1947

Reticulocyte studies were made by the darkfield method described by A. Nixet (Acta med Scand 1944). The identification of reticulocytes by the darkfield method of microscopy was very easy, the granulofilamentary substance appearing in the form of spots and threads of varying size and of yellow greenish hue.

Fifty healthy young men and women between 18 and 38 years were examined by this method, the percentage of reticulocytes was higher than with the usual method using 1 per cent solution of brilliant cresyl blue (darkfield 5 to 36 per mille, brilliant cresyl blue 0.5 to 14 per mille).

M.N.

DEVELOPMENT OF HEINZ BODIES M. Rejsek From the Clinic of Occupational Diseases, Charles University Prague Čas lékař čes 86 1183, 1947

The development of Heinz bodies could easily be followed in rabbits poisoned by dinitrobenzene. This toxic agent administered to the animals in the daily dose of 20 mg/Kg, provoked a hemolytic anemia with a steady decrease of hemoglobin and the red blood cells so that by the seventh day the number of red blood cells fell to one fifth of the original count. Heinz bodies appeared in the red cells as soon as the second day, they were attached to the surface of the cell by a kind of pseudopod which finally disappeared and the Heinz body was set free to circulate in the blood stream. Nile blue sulfate was the best dye for the supravital staining of the Heinz bodies.

M.N.

PLASMA IRON IN BLOOD DISEASES L. Donner From the 2nd Medical Clinic, Charles University, Prague Čas lékař čes 86 111, 1947

Plasma iron determinations were made in patients suffering from various blood dyscrasias. Decrease of plasma iron was found in acute or chronic blood loss (37 cases), in chlorosis (1 case), in hypochromic anemia (5 cases), in polycythemia (5 cases) and in chronic leukemia (8 cases), increase of plasma iron was found in aplastic anemia (6 cases) and in pernicious anemia (26 cases).

Influence of treatment on plasma iron was very marked in some cases, increase could be observed in chronic leukemia and in polycythemia following x-ray therapy, decrease to subnormal values occurred in pernicious anemia following liver therapy.

M.N.

FOLIC ACID THERAPY, ITS EFFECT AS OBSERVED IN TWO PATIENTS WITH PERNICIOUS ANEMIA AND NEUROLOGIC SYMPTOMS. By S. D. Jacobsen, L. Berman, A. R. Axilrod and E. C. Vander Hide From Wayne University College of Medicine and City of Detroit Receiving Hospital, and the Anemia Laboratory Harper Hospital Detroit Michigan J. A. M. A. 137 825-827, 1948

This is an additional report emphasizing the occurrence of neurologic relapse in patients with pernicious anemia under treatment with folic (pteroylglutamic) acid. Two patients aged 78 and 62 respectively, showed good hematologic, clinical, and, initially, neurologic remissions during treatment with folic acid. In both instances, numbness and tingling of the extremities improved, and in the second case where drowsiness, confusion, and irrationality were present, these symptoms also disappeared. On maintenance doses of folic acid, however (10 mg daily by mouth) paresthesiae recurred, and these and other neurologic symptoms and signs progressed despite increase in the dosage of the drug. Liver extract was ultimately given instead to each patient with apparently satisfactory response.

It is of interest in these, as in other similar cases, that the paresthesiae initially present disappear on treatment with a drug which subsequently allows their redevelopment. One wonders whether originally the paresthesiae were not, perhaps, on a noncentral basis, and that at the time of their recurrence—together with vibratory sensation changes, position sensation changes etc—they are due to a lesion different from that which caused them initially. At any rate liver extract and not folic acid alone, seems necessary for the satisfactory clinical treatment of such cases.

S E

## HEMOGLOBIN AND HEMOGLOBIN METABOLISM

THE EFFECT OF STROMA FREE HAEMOGLOBIN ON THE ISCHAEMIC KIDNEY OF THE RABBIT. *A W Badenoch and E M Darmady*. From the R. A. F. Hospital, Wroughton, England. Brit J Exper Path 29 215-223 1948

The authors conducted a series of experiments in rabbits combining right nephrectomy and left renal artery occlusion with or without the subsequent injection of stroma free hemoglobin. The results show that hemoglobin per se is not toxic and that renal damage must precede a detrimental effect from either hemoglobin or its derivatives.

O P J

CYANOSIS IN TREATMENT WITH SULFONAMIDES. *W Henbier and M Kesse*. From the University Institute of Pharmacology, Berlin (Germany). Schweiz med Wchnschr 77 1337-1339 1947

The authors critically discuss recent publications and maintain their formerly given opinion that methemoglobin and sulfhemoglobin have to be considered as the primary reason for cyanosis in sulfonamide treatment. They agree, though, that under special conditions further causes may intervene.

C.M

EVALUATION OF SOME METHODS OF HEMOGLOBIN DETERMINATION. *M. Rejškova and K. Rejšek*. From the Clinic of Occupational Diseases, Charles University, Prague. Čas lék čes 86 237, 1947

The results of hemoglobinometry, obtained with Sica hemometer were compared with those of Sahli's acid hematin method and of the photometric procedure of Heilmeyer Mutius, with the Sica hemometer and the photometric procedure. oxyhemoglobin is reduced to hemoglobin by sodium hydro-sulfite.

Sica hemometer proved to be the most reliable apparatus of hemoglobinometry. It was more exact than the procedure of Heilmeyer and Mutius. Sahli's method using acid hematin is very unreliable and should be discarded from scientific laboratory work.

The results obtained with any one of the procedures were compared according to statistical methods.

M.N

SOME PHYSICO-CHEMICAL PROPERTIES OF THE BLOOD BILIRUBIN. *M Netoušek*. From the Medical Department State Hospital Motol, Prague. Čas lék čes 86 799 1947

The solubility of the so-called indirect bilirubin in chloroform was discovered by Drer and the author in 1927. Independently of Yllpö (1913) and Grunenberg (1923) the nature of this phenomenon has not yet been elucidated.

In cancerous sera bilirubin may be soluble in ether. This unusual property of the blood bilirubin observed first by Ascoli (1935) and Albers and Merten (1940) has been found to be fairly constant and may be of some use in discriminating calculous and cancerous obstruction of the common bile duct. Further studies in this direction are desirable.

M.N

## BLOOD TRANSFUSION

**EXSANGUINATION TRANSFUSION IN THE TREATMENT OF ERYTHROBLASTOSIS FETALIS** *A. Raška and A. Bernard*  
From the State Health Institute and the Maternity Department of the City Hospital Prague Čas  
lék čes 86 1517 1947

A description of three successfully performed exsanguination transfusions is given. All were Rh positive infants born of Rh negative mothers and free Rh antibodies could be demonstrated in their sera in a high titer, the sera of their mothers contained Rh antibodies in a high titer as well.

A simple syringe technic was used in these transfusions. Native blood of the donor was given into the left saphenous vein (in the third case also into the cubital vein) and the blood was let out from the opened right radial artery or its branch. In the first case 430 cc. of blood were transfused and 300 cc. of blood were withdrawn; as this proved not to be sufficient the transfusion was repeated so that a total of 880 cc. of blood were transfused and 470 cc. withdrawn. In the second case 450 cc. of blood were transfused in one session and 380 cc. of blood withdrawn. In the third case, 590 cc. of blood were transfused and 430 cc. withdrawn. The transfusion lasted from 50 to 90 minutes. The results were satisfactory; all three patients did well. No heparin was used.

M N

**DENATURED VEAL PLASMA TO SUBSTITUTE HUMAN BLOOD AND PLASMA FOR TRANSFUSION PURPOSES** *J. Milka, Vlad. Rapant and B. Zapletal*  
From the Institute of Physiology and the Department of Surgery Palacky University Olomouc Czechoslovakia Čas lék čes 86 33 1947

Denatured veal plasma was prepared according to the method indicated by Massons (Lancet 2 341 1946); the denaturation of plasma proteins was effected by formalin and heat. This liquid was completely devoid of any antigenic or toxic properties; it had the same usual colloid osmotic pressure as before and did not provoke any sensitization in the recipient's body. The denatured veal plasma can therefore be considered a most perfect substitute of human blood or plasma for transfusion purposes; it is claimed.

M N

**THE BLOOD BANK IN THE STATE HEALTH INSTITUTE OF PRAGUE** *Stolzer, Štěrbová*  
State Health Institute Prague Čas lék čes 86 26, 1947

The distribution of blood groups has been determined in 6478 inhabitants of Bohemia. The results were: Group O 37.8 per cent, group A, 41.5 per cent, group B 14.1 per cent, group AB 6.6 per cent, subgroup A<sub>1</sub> 89.3 per cent, subgroup A<sub>2</sub> 10.7 per cent, subgroup A<sub>1</sub>B 70 per cent, subgroup A B 30 per cent, group M 33 per cent, group N 15 per cent, group MN 52 per cent.

Among the universal donors, only 20 per cent had a low agglutination titer.

M N

**IS PLACENTAL BLOOD SUITABLE FOR TRANSFUSION?** *V. Rešek*  
From the Maternity Hospital in Prague Čas lék čes 86 1246 1947

The author preserved and stored placental blood taken from 1000 parturient women and found the procedure to be harmless to the mother as well as to the baby. This blood was safely used in 57 transfusions performed in the hospital or elsewhere and its biologic value was found to be perfect. The same resulted from physicochemical and biologic investigations of the placental blood performed by the author. Its high content in hemoglobin, calcium and hormones makes it very suitable for transfusion purposes; the absence of isoagglutinins or their low titer makes the transfusion of placental blood a safe procedure. There is no danger of sensitization if repeated transfusions are administered. The cost of the placental blood is insignificant and the technic is simpler than that of taking venous blood.

By storage of placental blood the task of a blood donor service is made easier and the realization of a satisfactory transfusion service even in small county hospitals is facilitated. All maternity hospitals and all departments of obstetrics should store placental blood systematically and ought thus be included into the network of the transfusion service. With two thousand deliveries yearly it could be possible to store at least one hundred liters of blood and in this way the maternity hospital should be able to supply the whole district. The technic of preservation and storage of the placental blood is simple and can easily be performed anywhere.

M N

THE SURVIVAL OF THE VIRUS OF FOOT AND-MOUTH DISEASE IN BLOOD AT 37°C J B Brooksby From the Research Institute Pirbright, Surrey, England Brit J Exper Path 29 10-19 1948

During certain preliminary experiments it was noticed that the virus of foot and mouth disease survived longer in citrated blood than in defibrinated blood Brooksby has shown that the presence of calcium ions in guinea pig blood or serum hastens the inactivation of the virus at 37°C Other detalcifying anticoagulants such as sodium fluoride and potassium oxalate had the same effect as citrate in that the inactivation was prolonged The virus in heparinized and defibrinated blood behaved similarly Further studies may reveal that the effect of the Ca ion may be direct on the virus or it may be on some enzyme system

## LEUKOCYTES AND LEUKOCYTIC DISEASE

NEUROLOGICAL MANIFESTATIONS IN LEUKEMIA J Libánský and E Ponča From the 1st Medical Clinic and the Clinic of Nervous Diseases Charles University Prague Čas lěk čes 86 1244 1947

Three cases of leukemia with involvement of the C N S are reported in this paper

Case 1 A male of 36 years Severe headache for three weeks followed by impaired vision of the right eye, nausea and signs of meningeal irritation Acute myelogenous leukemia with 73.6 per cent myeloblasts was found at blood examination Autopsy revealed a tumor like infiltration of the C N S especially of the dura mater on both the convexity and the base

Case 2 A male of 21 years Intercostal neuralgia followed fourteen days later by signs of spinal compression, blood examination revealed the presence of acute myelogenous leukemia with 44 per cent myeloblasts Autopsy showed an epidural infiltration of Th<sub>II</sub> to Th<sub>VIII</sub> On the inner side of the sternum a flat tumor 7 x 4 cm was found, consisting of oxydase positive myeloid elements, this substernal tumor, as well as the epidural infiltration and the bone marrow had a definite greenish color so that the leukemia proved to be of a chloromatous character

Case 3 A man of 53 years suffering from chronic lymphatic leukemia, developed herpes zoster, the histologic examination, performed at autopsy showed a massive leukemic infiltration of the intervertebral ganglion and of the nerves supplying the area affected by the herpes zoster

The authors reviewed the literature and collected about 300 cases of leukemia showing neurologic symptomatology The neurologic lesion most frequently observed in leukemia is a spinal cord lesion resulting in paraplegia, next in frequency follows hemiplegia caused by cerebral hemorrhage and leukemia with signs and symptoms of a cerebral tumor with or without papilledema Lesions of the cranial nerves, especially the 7th bulbar paralysis damage of the Gasserian ganglion lesions of other cranial nerves peripheral nerve lesions symptomatic herpes zoster and meningeal lesions are less frequently encountered

The leukemic lesions of the C N S are due to leukemic infiltration or to hemorrhage primary degenerative changes analogous to funicular myelosis of pernicious anemia are quite exceptional and their existence would be acceptable in only some cases associated with severe anemia of long duration

CHEMOTHERAPY OF NEOPLASTIC DISEASE D A Karnofsky From the Sloan Kettering Institute and Memorial Hospital N Y C New England J Med 339 1948 1 Methods of approach 226-230 2. Trends in experimental cancer 260-270. 3 Agents of clinical value 299-305

This authoritative article deals in section 1 with the various investigative approaches to treatment of neoplastic disease and with methods of evaluating the effect of test substances on tumor tissue Section 2 summarizes the evidence for the experimental use of biologic products (bacteria molds and protozoa on urine and tissue preparations vitamins hormones) cell poisons (nitrogen mustards urethane colchicine podophyllin) carcinogenic agents radioactive substances and miscellaneous compounds (dyes b-hydroxyde stilbamidine enzyme poisons)

Of practical interest is the discussion of clinical use of these agents particularly the detailed discussion of nitrogen mustard therapy of blood dyscrasias and lymphoma The author also comments on effectiveness of radioactive phosphorus urethane and Fowler's solution in this regard

C A F

TEMPORARY REMISSIONS IN ACUTE LEUKEMIA IN CHILDREN PRODUCED BY FOLIC ACID ANTAGONIST 4 AMINOPTERYL-GLUTAMIC ACID (AMINOPTERIN) *S. Farber, L. K. Diamond, R. D. Mercer, R. F. Sylvestre Jr. and J. A. Wolff* *New England J. Med.* 238: 787-793, 1948

The authors report on 16 infants and children with acute leukemia treated with aminopterin. In this group, it showed clinical, hematologic, and pathologic evidence of improvement. Detailed accounts of the 5 most favorable cases are given. The observations extend for no longer than three months after the beginning of therapy. Stomatitis with ulceration was mentioned as a toxic manifestation of the drug.

While the immediate effect of aminopterin on the course of leukemia is dramatic in some instances, the preliminary nature of this report and the severity of the toxic manifestations of this drug should be emphasized.

C.A.F.

DIFFUSE PLASMA CELL MYELOSIS. REPORT OF A CASE IN WHICH IT SIMULATED APLASTIC ANEMIA ON POST MORTEM EXAMINATION *S. E. Schwartz, B. E. Armstrong, E. Loeffler and W. Maurer*. From the Department of Pathology and the Hektoen Institute for Medical Research, Cook County Hospital, Chicago. *Ill. Arch. Path.* 45: 380-384, 1948.

If a case of multiple myeloma has a diffuse involvement of the marrow without an infiltration of other organs, the hematologic pathologist might be misled by the gross appearance at necropsy. The authors report such a case which had a diffuse myelomatosis of the marrow without any localizing lesions, tumor formation or peripheral plasmacytosis.

O.P.J.

PLASMOCYTIC LEUKEMIA *F. Leberer*. From the 3rd Medical Clinic, Charles University, Prague. *Čas. lékař.* 86: 1366, 1947.

A rare observation of plasmocytic leukemia in a man of 42 years is reported. Duration of the disease from the onset, was fourteen months. The blood picture showed a slightly macrocytic anemia, moderate leukocytosis of 38,000 and 62 per cent myeloma cells.

M.N.

TREATMENT OF MULTIPLE MYELOMA WITH STILBAMIDINE. CLINICAL RESULTS AND MORPHOLOGIC CHANGES *By I. Snapper*. From the Mount Sinai Hospital, New York, N.Y. *J. A. M. A.* 137: 513-516, 1948.

At the original time of this report (June 1947) some 35 patients with multiple myeloma had been treated with stilbamidine, a compound found to be effective in kala-azar, and originally tried in myeloma because of the common factor of hyperglobulinemia in the two otherwise unrelated conditions. Dramatic relief of pain is recorded by the author in some cases, and at least partial relief was noted in 80 per cent of his cases. There was no effect, however, on the underlying disease itself, or on its biochemical alterations (Bence-Jones proteinuria, hyperglobulinemia). As previously noted, the striking finding was the development in the cytoplasm of myeloma cells—and in these cells only—of granules which consisted of a conjugate of stilbamidine with the ribonucleic acid of these cytoplasmic granules. The specificity of the stilbamidine for such cytoplasm suggested a fundamental characteristic of the plasma cell which distinguished it from all other blood cells. The relationship in either the cause or the treatment of the disease, however, was still to be determined.

S.E.

OBSERVATIONS IN GUINEA PIGS FOLLOWING INJECTION OF SPECIFIC HEMATOPOIETIC SUBSTANCES DERIVED FROM URINE OF HUMAN LEUKEMIC SUBJECTS. *A. Sawitsky and L. M. Meyer*. From Department of Therapeutics, N.Y.U. College of Medicine, New York City. *Am. J. Path.* 44: 1117-1135, 1948.

Extracts of urines from patients with myeloid or lymphoid leukemia were prepared by chloroform extraction. These were separated into carbinols and noncarbinols by succination. Ether was used in a second type of extraction. Guinea pigs were injected either subcutaneously or intramuscularly. Examination of lymph nodes, spleen, liver, adrenals, kidneys, lung and bone marrow showed varying degrees of hyperplasia and infiltration depending upon the extract. Carbinol (lymphoid) extracts produced a specific

lymphoid reaction and noncarbinol (myeloid) extracts produced a specific myeloid reaction. The results of these experiments justify further attempts to purify and concentrate the active factors involved.

**CYCLIC AGRANULOCYTOSIS** R. *Muratori* From the 2nd Medical Clinic Charles University, Prague Čas lék ces 86 1546, 1947

In a girl of 15 years suffering from agranulocytosis following immoderate use of amidopyrine (548 grams within one year) a marked recurrence of fever, leukopenia and appearance of necrotic areas in the gums could be observed in connection with the menstrual periods. Penicillin and transfusion were in effective but it was found that folic acid and pyridoxine were followed by a complete disappearance of all signs and symptoms.

M N

## THE SPLEEN

**SPLENOMEGALY** D. *Symmers* From the Laboratories of Pathology Bellevue Hospital New York City Arch Path 45 385-409 1948

This is a general review which, for convenience sake has assembled the splenomegalies into the following groups. Those of circulatory origin, mechanical, metabolic, blood dyscrasias, unknown nature and finally neoplastic and cystic splenomegalies. This excellent article has drawn upon material obtained from 23,792 necropsies at the Bellevue Hospital during the past 30 years.

O P J

**HAMARTOMA OF THE SPLEEN. REPORT OF THREE SURGICAL CASES** W. G. *Kirkland* and J. R. *McDonald* From the Division of Surgery Mayo Clinic Rochester Minn Arch Path 45 371-379 1948

Certain neoplasms consisting of an abnormal mixture of the normal components of an organ have been referred to as hamartomata ever since the term was proposed by Albrecht in 1904. Kirkland and McDonald studied splenic neoplasms removed surgically and found 3 cases which seemed to fall into this category. One of the outstanding features of each specimen was the ramifying spaces or channels lined by endothelium. It has been suggested that this is a specific benign tumor and that perhaps some hamartomata of the spleen previously reported actually belonged to this group.

O P J

**THE EFFECT OF HEAVY MUSCULAR WORK ON THE VOLUME OF CIRCULATING RED CORPUSCLES IN MAN** G. *Nylin* From Sabbatsberg's Hospital Stockholm Sweden Am J Physiol 149 180-4 1947

Since Barcroft's demonstrations in 1923-1925 that the spleen of dogs is capable of storing large quantities of blood for use in emergencies (exercise, administration of epinephrine), the reservoir function of the human spleen has been considered correspondingly well established. Little experimental verification of this thesis, however, has been offered.

In the present report Nylin tested whether severe muscular work could be shown to result in splenic contraction and emptying of the postulated stored blood in human adults. He injected blood containing labelled red blood cells (labelled with radioactive phosphorus) into 5 healthy men and took blood samples in ten and again in fifteen minutes after the injection. The subject was then made to do severe muscular work and two further blood samples were taken, the first at 25-32 minutes, the second at 27-39 minutes. All samples were subjected to radioactivity determinations in a Geiger-Müller counter. It had previously been shown by the author that the radioactivity of the blood remains constant for at least 60 minutes after such an injection; hence the volume of the circulating red cells could be measured by the radioactivity of the blood. Presumably, if any reservoir of blood was present which responded to the severe muscular exercise, discharge of red cells from this reservoir would change the radioactivity of the circulating blood.

Nylin found actually that there was no change in the specific activity of the blood after exercise within the time studies. For all the patients the mean circulating cell volume before work was 2,405 ml, as compared with 2,471 ml after work, and the mean circulating total blood volume before work was 4,934 ml, as compared with 4,855 ml after work. Since the amount of the red cells was unchanged, it

was concluded that there was no reservoir which empties red cells into the circulation after work. This result is in contrast with the work of Barcroft (on dogs), and with the commonly held opinions that epinephrine contracts the spleen and thereby increases the number of circulating red cells. If verified, these conclusions would be of great importance.

## BLOOD COAGULATION AND HEMORRHAGIC DISEASES

MANAGEMENT OF GASTRIC HEMORRHAGE USING TOPICAL THROMBIN. T. M. Rogers. J. A. M. A. 137: 1035-1036, 1948.

This is a clinical report of the cessation of severe gastric hemorrhage in two cases following the introduction into the stomach of a solution of topical thrombin.

Especially impressive is the dramatic cessation of repeated massive, almost-exsanguinating hemorrhage in the first case: a 64-year-old man with a prepyloric ulcer. This patient bled repeatedly and severely despite rest, sedation (including the desperate use of pentothal sodium intravenously), epinephrine, vitamin K, parenteral feeding. As a final measure, 10,000 units of thrombin mixed with 2.5 cc. of isotonic sodium chloride solution were given orally, and repeated three times daily for five days. No bleeding occurred after the first dose of thrombin, and the patient progressively improved.

Although it is impossible definitely to demonstrate cause and effect in a case of this type, the clinical data strongly suggest that the thrombin was responsible for the cessation of gastric hemorrhage, and recommend its further trial in other similar cases.

S.E.

THROMBOCYTOPENIC PURPURA FOLLOWING QUINIDINE. P. L. Nadelman, I. L. Leff, and C. D. Howe. From the Third (New York University) Medical Division, Goldwater Memorial Hospital, New York, N. Y. J. A. M. A. 137: 1219-1220, 1948.

According to the authors, this is the second recorded instance of the development of thrombocytopenia following the use of quinidine. (Less rare is thrombocytopenia following quinine.)

The patient was a 37-year-old woman who received 0.6 grams of quinidine daily because of supraventricular tachycardia in hypertensive rheumatic heart disease. After she had taken 6.0 grams of the drug in 11 days, she began to bleed from the gums, and was found to have petechiae, ecchymoses, thrombocytopenia (4,000 platelets per cu mm), increased bleeding time, positive capillary fragility tests, and poor clot retractility. In the bone marrow, megakaryocytes were normal in number and appearance, and the differential count of the marrow cells was normal. A blood transfusion was given, and the patient made a rapid recovery. Subsequently, a test administration of 0.1 grams of quinidine resulted in an identical exacerbation of the syndrome.

S.E.

EXCESSIVE HYPOPROTHROMBINEMIA DUE TO DICUMAROL: ITS TREATMENT WITH LYOPHILIZED PLASMA. S. W. Coziff, R. J. Cross, and D. V. Hays. From the Departments of Medicine and Surgery, Columbia University College of Physicians and Surgeons, New York. J. A. M. A. 138: 405-6, 1948.

The authors suggest the feasibility of using reconstituted lyophilized plasma in the emergency treatment of excessive hypoprothrombinemia due to over-dicumarolization.

The prothrombin time of such plasma was found to be normal (12.7 to 15 seconds; control 12 to 16 seconds), and the administration of 500 cc. of such plasma to 13 patients with high prothrombin times (43.0 to 97 seconds) was found to cause a prompt return of the prothrombin time of the patients' plasma to safe levels (actually 22 to 38 seconds). The effect was transitory, however, and in some patients had disappeared by as little as six hours. Since none of the patients in the group had clinical bleeding, any effect on the hemorrhage of hypoprothrombinemia could not be ascertained.

The method may be added to the more conventional ones for emergency treatment of over-dicumarolization, viz., the use of synthetic vitamin K and the transfusion of whole blood. It would have been of interest to determine how small an amount of plasma suffices to shorten the prothrombin time.

# NEWS AND VIEWS

## CONDENSATION OF THE FIRST TWO REPORTS OF THE COMMITTEE FOR CLARIFICATION OF THE NOMENCLATURE OF CELLS AND DISEASES OF THE BLOOD AND BLOOD-FORMING ORGANS\*

### THE TERMS AND DEFINITIONS FOR THE CELLS OF THE LEUKOCYTIC, THROMBOCYTIC AND ERYTHROCYTIC SERIES

Clarification and definition of terms is urgently needed for the sake of a common understanding in clinical usage and in teaching of medical students and technicians. The choice of a preferred term, it was agreed, should not be based merely on historical priority or common usage but, in general, should represent the simplest, clearest and most descriptive term. Eponyms and new terms should be avoided, wherever possible, without sacrifice of clarity. An effort should be made to attain consistency between related terms.

The various series of cells were considered. It was recommended that in table 1 the term listed at the left replace all terms listed at the right in referring to cells of a particular series or to a disease affecting any cell of that series.

No changes were suggested in the criteria in current use for determining the series to which a cell belongs. It is hoped, however, that the advances now being made in histochemistry will contribute more clearcut criteria than are available at present.

It is recommended that the term *leukocyte* be considered synonymous with white blood corpuscle and include all white cells of the blood and their precursors in the blood-forming organs. Its use should not be limited to cells of the granulocytic series, excluding cells of the lymphocytic, monocytic or plasmacytic series. This and other words derived from the same root should be spelled with a *k* and not a *c*: *leukocyte*, leukemia, not *leucocyte* or *leucemia*.

It is recommended that the descriptive terms for granulocytes: *neutrophil*, *eosinophil*, *basophil* and *azurophil* be spelled as indicated without a final *e*.

It is suggested that the name of the most undifferentiated of the cells of each series carry the suffix *blast*; the second stage the prefix *pro-* and except in the granulocytic series all cells that are more mature than the blast stage have names with the suffix *-cyte*. The name for the fourth stage in the granulocytic and erythrocytic series is to have the prefix *meta*. The terms *blast cells* and *pro cells* may be used to replace other terms for these stages of development when speaking of the stage of development as a whole or when the series to which the cells belong has not been identified.

It is recognized that the *blast cells* of each series are morphologically very similar, all having fine nuclear chromatin structure, usually demonstrable nucleoli and basophilic cytoplasm with or without azurophilic granules, so the prefix to be used will in many instances depend on the identification of the *pro-* stage associated with them.

*Fine chromatin structure* is defined as having the nuclear appearance of a background of homogeneous lighter staining parachromatin overlaid by a darker staining late net meshwork or finely stippled pattern.

\*Reprinted from the American Journal of Clinical Pathology 18 473 May 1948 and Vol 13 January 1949 with permission of the Editor and the publishers The Williams and Wilkins Company.

This condensation was made available by the Chairman of the Committee Dr. Edwin E. O'Rand, Portland, Oregon.

tern of basichromatin with no aggregation of the basichromatin into even a single clump of appreciable size staining darker than any other areas in the nucleus

A *nucleolus* is defined as a homogeneous blue staining area within the nucleus of a cell, which stains more like the cytoplasm than does any other part of the nucleus

The term *azurophil* should be applied to the granules seen typically in the cytoplasm of cells of the lymphocytic and monocytic series and the progranulocyte stage of the granulocytic series. The term *azurophil* is recommended, and not *azuric*, in describing these granules, since the term refers to an affinity for a particular dye and not to the color of the granules. These granules may be present or absent in any cell of the lymphocytic series and when present are usually coarse and in clumps. They are usually present in all cells of the monocytic series, including the monoblast. In the monocytic series they are usually fine, diffusely and uniformly scattered through the cytoplasm. If not seen in the monocyte or promonocyte, it usually indicates a faulty stain or poor visual definition in the microscope. These granules may be present or absent in any cell of the granulocytic series. They are rarely seen beyond the myelocyte stage except in disease. They are occasionally present in the cytoplasm of cells of the plasmacytic and erythrocytic series and constantly present in the cells beyond the blast stage in the thrombocytic series where they tend to be fine and few in the early stages and numerous and often clumped in the more mature stages.

TABLE 1 — *Recommended Terms and Terms to be Avoided when Referring to Cells of a Particular Series in a Disease Affecting any Cell of that Series*

Term to be used	Terms to be avoided
Lymphocytic	Lymphoid lymphatic, lymphogenous, lymphocyte, mononuclear
Granulocytic	Myeloid myelogenous, myelocyte, myelocytic, granulocyte, leukocyte leukocytic, leucocyte, leucocytic
Monocytic	Monocytoid monocytogenous, mononuclear, monocyte
Plasmacytic	Plasma cellular plasmacytogenous myeloma cell plasmacyte
Thrombocytic	Megakaryocytic platelet, thrombocyte
Erythrocytic	Erythroid erythrocytoid erythron, erythrocytogenous, erythrocyte

It is recognized that in each cell series there is a continuous development from the most undifferentiated to the most differentiated stage, that an infinite number of subdivisions are possible, and that any subdivision is arbitrary. The committee recommended the use of the minimum number of subdivisions which will provide essential information for diagnostic and prognostic purposes and defined the lines of division between these stages as clearly as possible, basing these divisions on a single easily identifiable feature. As far as possible, the feature selected to differentiate the different stages of development is one which could be recognized in either stained or supravital preparations, but it is realized that at present the majority of such decisions will be based on smears stained with Wright's stain or with one of the other Romanowsky stains. Even with these definitions, cells will be encountered where decision is difficult, in which case it is suggested that the cell be arbitrarily placed in the more differentiated category.

Names were selected for each of the cells, which were acceptable to all members present and which, in the opinion of the committee, were least likely to be confusing.

The recommended terms and the terms to be avoided are listed in table 2.

*It is not the intention of the committee to imply from its recommendation of terms to be used that the origin of all these cells has been settled.*

It is recognized that to ensure flexibility and for certain specialized purposes finer

TABLE 2.—*Recommended Terms and Terms to be Avoided when Referring to Specific Cells of the Blood and Blood Forming Organs*

<i>Name of series</i>	<i>Term to be used</i>	<i>Terms to be avoided</i>
Lymphocytic	Lymphoblast	Myeloblast, hemocytoblast, lymphoidocyte stem cell, lymphocyte
	Prolymphocyte	Large lymphocyte pathologic large lymphocyte atypical leukocytotic lymphocyte monocyte immature lymphocyte
	Lymphocyte	Small medium or large lymphocyte, normal lymphocyte, small, medium or large mononuclear
Monocytic	Monoblast	Myeloblast hemocytoblast, lymphoidocyte lymphocyte, stem cell, immature monocyte
	Promonocyte	Premonocyte, hemohistioblast immature monocyte Ferrata cell
	Monocyte	Large mononuclear transitional, plasmacyte endothelial leukocyte histiocyte resting wandering cell
Granulocytic	Myeloblast	Granuloblast hemocytoblast, lymphoidocyte lymphocyte stem cell
	Progranulocyte	Promyelocyte II leukoblast myeloblast promyelocyte promyelocyte progranulocyte A
	Myelocyte	Granulocyte, myelocyte B, non filament class I
	Metamyelocyte	Metagranulocyte juvenile, myelocyte C, non filament class I
	Band Cell	Staff cell stab cell non filament, class I rod nuclear polymorphonuclear stabkernige, rhabdocyte non segmented
	Segmented	Polymorphonuclear filamented class II, III, IV or V lobocyte
Plasmacytic	Plasmablast	Myeloblast, hemocytoblast, lymphoidocyte lymphocyte, stem cell, lymphoblastic plasma cell myeloma cell
	Proplasmacyte	Türk cell, Türk irritation form lymphoblastic or myeloblastic plasma cell myeloma cell
	Plasmacyte	Plasma cell Unna's plasma cell, Marschalko's plasma cell plasmacytotic lymphocyte myeloma cell
Thrombocytic	Megakaryoblast	Megalokaryoblast
	Promegakaryocyte	Premegalokaryocyte
	Megakaryocyte	Megalokaryocyte
	Thrombocyte	Platelet thromboplasmic
	Disintegrated cell	Senile cell smudge basket cell smear cell dgerat dec

subdivisions may be necessary than those herein recommended. It is suggested that in such case no change be made in the term or definition of the recommended major divisions but that *clearly defined* qualifying adjectives be used for these further subdivisions. Should new knowledge indicate that another major cell division is needed the evidence for this need, together with the suggested term, should be submitted for consideration by a permanent body which it is hoped will develop out of this committee.

The definitions decided on are as follows:

*Lymphoblast* Any cell of the lymphocytic series having fine chromatin structure in the nucleus. Cells of blast morphology associated with prolymphocytes should be tentatively classified as lymphoblasts.

*Prolymphocyte* Any cell of the lymphocytic series intermediate in morphology between the lymphoblast and the lymphocyte. It will always have too coarse a chromatin structure to fit the criteria for a blast and too fine a chromatin structure or too large a cell diameter to be classed as a lymphocyte. Usually but not always prolymphocytes are larger than 15 microns in diameter which is the upper limit for the lymphocyte.

*Lymphocyte* Any cell of the lymphocytic series having the morphology of those commonly found in the blood of healthy adults.

*Monoblast* Any cell of the monocytic series having fine chromatin structure. Usually nucleoli are visible. Cells of blast morphology found in association with promonocytes should be tentatively classed as monoblasts.

*Promonocyte* Any cell intermediate in morphology between the monoblast and the monocyte. It is differentiated from the monoblast by having an irregularly shaped nucleus and somewhat coarser chromatin structure and from the monocyte by the presence of one or more nucleoli.

*Monocyte* Any cell of the monocytic series having the morphology of those commonly found in the blood of healthy adults. It is differentiated from the promonocyte by the absence of nucleoli.

*Myeloblast* Any cell of the granulocytic series having fine chromatin structure and containing no specific granules. Usually nucleoli are visible. Cells of blast morphology found in association with progranulocytes should tentatively be classed as myeloblasts.

*Progranulocyte* Any cell of the granulocytic series which has a nuclear structure too coarse for that of a blast cell and which has not yet developed discernible specific granules. This term was selected rather than promyelocyte because of its clear relationship to the definition of granulocyte, given below, and because the term promyelocyte has been in wide use for cells which do contain specific granules. The reason that the terms granuloblast, granulocyte and metagranulocyte were not chosen was that the terms myeloblast and myelocyte were already in general use with essentially the definitions here given. This is true also for the term granulocyte which would otherwise have to be synonymous with the term myelocyte.

*Specific granules* Neutrophilic, eosinophilic or basophilic granules. This term does not include *azurophilic* granules.

*Granulocyte* An inclusive term to apply to any cell containing specific granules. The plural form *granulocytes* would therefore include all myelocytes, metamyelocytes, band cells and segmented cells whether neutrophils, eosinophils or basophils.

*Myelocyte* Any cell containing specific granules, with a round or oval nucleus. It is distinguished from the progranulocyte by the presence of specific granules and from the metamyelocyte by the absence of indentation in the nucleus. It may be further subdivided at the option of the user into early and late stages but the definition of early or late should be clearly stated in any publication.

This and all subsequent cells of the granulocytic series should be additionally characterized as neutrophil, eosinophil or basophil.

*Metamyelocyte* Any cell of the granulocytic series having specific granules in the cytoplasm and a nucleus intermediate in shape between that of the myelocyte and the band cell. The nucleus usually has an indented oval shape, resembling a bean or kidney.

**Band cell** Any cell of the granulocytic series which has a nucleus that could be described as a curved or coiled band, no matter how marked the indentation, if it does not completely segment the nucleus into lobes connected by a filament. It is differentiated from the metamyelocyte by an appreciable length of the nucleus having parallel sides, and from the segmented neutrophil by having no indentation which could be described as a filament.

**Segmented cell** Any cell containing specific granules in which the lobes of the nucleus are connected by a filament. A *filament* is defined as a threadlike structure. Since at times in viewing a three-dimensional object from one direction, it is impossible to be certain whether two parts of the nucleus are connected by a filament or band, it is suggested that such cells always be placed in the segmented category, since this is the more differentiated and more common cell.

The term *toxic neutrophils* followed by a 1 to 4+ designation is recommended for the grading of toxic granules, basophilia of the cytoplasm, vacuoles and condensation of nuclear chromatin in the neutrophils, since its meaning is clear although it is recognized that it is not an adequately descriptive term. The grading should depend more on the degree of change than on the percentage of the cells involved and should be recorded in the report whenever the degree of change exceeds 2+.

**Plasmablast** Any cell of the plasmacytic series having fine chromatin structure in the nucleus. Cells of blast morphology found in association with proplasmacytes are usually seen only in plasmacytic leukemia or plasmacytic sarcoma. The cytoplasm tends to be more opaque in staining than in the other leukocytic blast cells.

**Proplasmacyte** Any cell of the plasmacytic series with a nuclear structure too coarse for that of a blast cell but with one or more nucleoli present.

**Plasmacyte** A cell characterized by extremely coarse chromatin structure with the deeply staining chromatin of the nucleus aggregated into large sharply demarcated clumps. It is differentiated from the proplasmacyte by the absence of nucleoli. The cytoplasm of all cells of the plasmacytic series tends to be deeply basophilic and opaque in appearance. Azurophilic granules may be present or absent but are more commonly absent.

**Megakaryoblast** Any cell of the thrombocytic series having a nucleus with fine chromatin structure. Usually these are larger than the other blast cells.

**Pronegkaryocyte** Any cell of the thrombocytic series with a nucleus containing nucleoli but having a chromatin structure too coarse for a blast cell. The nucleus is usually similar in shape to that of the megakaryocyte. Fine azurophilic granules are usually diffusely scattered through the cytoplasm.

**Megakaryocyte** Any nucleated cell of the thrombocytic series in which nucleoli are not discernible. The azurophilic granules are often aggregated into clumps. Megakaryocytes and pronegkaryocytes are typically much larger than other cells found in the marrow.

**Thrombocyte** Any cell of the thrombocytic series containing no nucleus in other words any non nucleated fragment of megakaryocytic cytoplasm containing azurophilic granules similar to those of the mature megakaryocyte.

The term *thromboplastid* was recognized as being anatomically correct but it was felt that to be consistent with the use of the term *erythrocyte* and to permit the use of thrombocytic and erythrocytic in describing these cell series the suffix *-cyte* was preferable for these two non nucleated forms.

**Disintegrated cell** Any cell of any series in which the cytoplasmic outline has been disrupted or the nuclear chromatin is no longer surrounded by a membrane excluding the changes in the nucleus that occur in mitotic division. Disintegrated cells should be recorded as such in the differential report even though they could be identified by dispersed granules. They should be counted even if only shreds of nuclear material are discernible since they are undoubtedly included in the total leukocyte count.

It was the decision of the committee that none of the terms in current use for the nucleated cells of the erythrocytic series could be recommended because mutually exclusive definitions for the same term have been used in different schools of hematology, because these are all inconsistent with the terms already recommended by the committee for the other series of cells, and because the use of the suffix *-blast* for the most differentiated nucleated cell of the erythrocytic series has been a constant source of confusion to medical students and medical technologists for in

all other series -blast has been used exclusively for the least differentiated cell. The logical terms *erythroblast*, *proerythrocyte*, *erythrocyte* and *metaerythrocyte* were impossible to use because of the wide employment of the terms *erythroblast* and *erythrocyte* with other meanings than would be intended for them in the present recommendations. After considering many suggestions and consulting Latin and Greek authorities, the Latin syllables *rubri*, meaning red, were selected as least likely to be misinterpreted because this stem is familiar in medical terminology, having been used in *polycythemia rubra vera* and in the derivation of many other words in which the root *rub* denotes red, such as *rubicund* and *rubefacient*. Other stems considered were the Greek terms *roso*, rose, *rosino*, rosy, *erythe*, red, *porphyro*, deep-red, *pyrrho*, flame-colored, and *cirrho*, tawny-yellow, but these were discarded as likely to be more difficult to pronounce and learn.

TABLE 3 — Recommended Terms and Terms to be Avoided when Referring to Specific Cells of the Erythrocytic Series

Name of series	Term to be used	Terms to be avoided
Erythrocytic	Rubriblast	Erythroblast megaloblast pronormoblast promegaloblast, normoblast, hemocytoblast stem cell myeloblast lymphoidocyte karyoblast
	Prorubricyte	Erythroblast megaloblast pronormoblast normoblast macro-normoblast macroblast prokaryocyte
	Rubricyte	Normoblast pronormoblast macronormoblast erythroblast polychromatophilic normoblast karyocyte
	Metarubricyte	Normoblast erythroblast metakaryocyte
	Reticulocyte*	
	Erythrocyte	Red blood cell erythroplastid normocyte, akaryocyte

\* It is recommended that the reticulocyte stage be considered a subdivision of the erythrocyte stage.

The best solution that could be found for the problem of clearly indicating the changes in nuclear morphology commonly seen in cells of the erythrocytic and granulocytic series in pernicious anemia and other macrocytic anemias which respond to liver extract and folic acid was to coin a new adjective phrase which could be used to qualify the recommended terms for any of the cells of these two series, or to describe the marrow and blood pictures as a whole. The terms *macrocytoid*, *macroid*, *megalo-*, and *megaloid* were considered, but none was acceptable to the authorities consulted or to the majority of the members of the committee. The adjective phrase *pernicious anemia type* was recommended by the committee after extensive deliberation, to be used in full in any publication, although in the laboratory and clinic it can conveniently be abbreviated to *P A*. The use of such an adjective phrase should be perfectly clear and it has the great advantage over *megalo-blastic* that it can be applied to cells of the granulocytic as well as of the

erythrocytic series and also to the marrow and blood pictures. Eventually, if the anti-pernicious anemia principle is identified and given a short, simple name, a term analogous to *afolic* may be substituted by committee action for the presently recommended adjective phrase.

The names selected by the committee for the stages of differentiation are given in table 3, and their definitions follow. It should be re-emphasized, as was pointed out in the first report,<sup>1</sup> that no changes are suggested or implied by these definitions for the criteria in current use for determining the series to which a cell belongs. The recommended definitions are meant to point out only the one essential differential characteristic for determining the stage of differentiation, and they are not intended to be complete descriptions of all cell stages, or of normal and pathologic variants. For these finer details of identification readers are referred to standard textbooks of hematology.

**Rubriblast.** Any cell of the erythrocytic series having fine chromatin structure in the nucleus. Nucleoli are usually discernible. A stippled chromatin pattern is more common than the lace-net pattern usually seen in other blast cells.

**Prorubricyte.** Any cell of the erythrocytic series in which one or more nucleoli are discernible in the nucleus and which has a chromatin structure too coarse to be classified as a rubriblast.

**Rubricyte.** Any cell of the erythrocytic series having definite structure of the nuclear chromatin, but containing no discernible nucleoli. This stage is differentiated from the prorubricyte by the absence of nucleoli in the nucleus and from the metarubricyte by not having a pyknotic, fragmented or partially extruded nucleus. Some may wish to subdivide and qualify this stage—or other stages—further into basophilic, polychromatic or normochromatic rubricytes according to the amount of hemoglobin present in the cytoplasm.

**Metarubricyte.** Any nucleated cell of the erythrocytic series having a pyknotic, fragmented, partially extruded or partially autolyzed nucleus. *Pyknotic* describes a dense, solid, structureless nuclear mass. The phenomenon of karyorrhexis or fragmentation of nuclei should be clearly distinguished from the occurrence of double, well formed nuclei which are occasionally seen in prorubricytes and rubricytes as well as in other cells which may divide amitotically.

**Reticulocyte.** Any non nucleated cell of the erythrocytic series in which, when supravitality stained—usually with brilliant cresyl blue—one or more granules or a diffuse network of fibrils are discernible. All reticulocytes are included under the term erythrocytes since, without a special stain, reticulocytes are indistinguishable from erythrocytes.

**Erythrocyte.** Any non nucleated cell of the erythrocytic series.

**Pernicious anemia type.** The qualifying adjective phrase to be applied to any cell of the erythrocytic or granulocytic series and to the marrow and blood pictures as a whole to indicate the presence of the morphologic changes characteristically seen in pernicious anemia and other macrocytic anemias which respond to liver extract or folic acid therapy. In the nucleated cells of the erythrocytic series the major feature of this change is a relative increase in the pale staining parachromatin with a corresponding decrease in the deep-staining basichromatin. In the cells of the granulocytic series the characteristic change is the presence of giant forms having very bizarre nuclei and in the segmented neutrophils the occurrence of many cells with more than five lobes.

Each name recommended for the cells of the erythrocytic series clearly indicates the stage of differentiation. The use of the qualifying adjective phrase, *pernicious anemia type*, with the name of the cell stage will equally clearly indicate that a cell shows the alterations in morphology typically seen in the marrow or blood of untreated pernicious anemia, as contrasted with the corresponding cell which is unqualified as to terminology. Pre-existing confusion in the usage of terms for

nucleated erythrocytes is thought to be clarified by the recommended terminology as illustrated by the following example *Megaloblast* as in current use by some hematologists is synonymous with *rubriblast*, as herein recommended and defined, but as used by other hematologists it is synonymous with the presently recommended term *pernicious anemia type prorubricyte*

It is, of course, understood that modifying adjectives may be applied to any of the recommended terms in describing results of investigation, but if these terms are to gain general acceptance they should not be given any new definitions except by general action of the committee

#### INTERNATIONAL SOCIETY OF HEMATOLOGY

Through an unfortunate error in publication, the names of the two Secretaries-General were omitted from the list of officers elected at the Buffalo Congress of last August (*Blood* 3 1313, 1948). The complete list of new officers is as follows

*President* Professor Sir Lionel Whitby, Cambridge, England

*Vice-Presidents* For North America William Dameshek, Boston, Mass

For South America Luis Sandoval S, Santiago, Chile

For Europe G DiGuglielmo Naples, Italy

*Secretaries General* Western Hemisphere Sol Haberman, Dallas, Texas

Europe Marcel Bessis, Paris, France

*Counsellors for the United States* Charles A Doan, Columbus, Ohio

Edwin E Osgood, Portland, Ore

Ernest Witelsky, Buffalo, N Y

A more complete report of the Congress, of which the November 1948 note was intended as preliminary, will be published in a future issue of *Blood* as soon as the large amount of wire-recorded material can be transcribed and edited. The publication of a volume of the Proceedings is presently being discussed

Acting on suggestions made to the Editorial Board, the Journal is pleased to announce the following revision in subscription policy. Holders of Internships, Residents and Fellowships within the United States may now obtain one or two year subscriptions to *Blood* at the reduced rate of \$9 per year. Those wishing to take advantage of this offer should provide the publisher with their hospital addresses and positions

### HEMOPHILIA A CLINICAL STUDY OF FORTY PATIENTS

By CHARLES S. DAVIDSON, M D, ROBERT D. EPSTEIN, M D, GEORGE F. MILLER, M D, AND F. H. L. TAYLOR, PH D

#### INTRODUCTION

SINCE 1803 when hemophilia was first accurately described by Dr John C Otto,<sup>1-3</sup> investigators of this disease have centered their efforts chiefly in the elucidation of its hereditary nature and in the study of the constant defect in blood coagulation. In the study presented here we wish to emphasize certain clinical manifestations of the disease and methods of practical therapeutic management which have been learned in this laboratory during the last ten years in the course of a study of the defect in coagulation of the blood in individuals with the disease. The deep interest of Dr George R. Minot in hemophilia began in 1918 when he and Dr Roger I. Lee first demonstrated in this country that whole blood transfusions were effective in shortening the blood coagulation time.<sup>4</sup> He has been the guiding spirit of the investigative work in hemophilia in this laboratory, and this presentation is dedicated to him. His guidance in this problem has given experience to many young men in the methods of clinical investigation.

Hemophilia is an hereditary disease limited to males, those afflicted exhibiting both impaired coagulability of the blood and a strong tendency to bleed especially following trauma. Although there may be variations in the frequency and severity of hemorrhagic episodes, the disease is always present for life. Transmission of the disease is always through the female to the second generation, the genes being sex-linked and recessive. Although the possibilities exist of both a first generation male with hemophilia as well as a female with the disease, authenticated cases are not known.

Although Otto was the first to bring the true nature of the disease into clear focus, there is evidence that certain aspects had been known in ancient times by the Arabs and the Jews. Bullock and Fildes<sup>5</sup> in their classical monograph on the disease report descriptions of a condition resembling hemophilia by Albucasis in the tenth century. Among the recent general articles or monographs on hemophilia are those of Birch,<sup>6</sup> Howell,<sup>7</sup> Stetson and Lozner,<sup>8</sup> Quick,<sup>9</sup> Davidson and McQuarrie,<sup>10</sup> Ely,<sup>11</sup> Mills,<sup>12</sup> MacFarlane,<sup>13</sup> and Kark.<sup>14</sup>

From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) and the Department of Medicine, Harvard Medical School, Boston, Mass.

This study was aided in part by a grant from the Smith Kline and French Laboratories, Philadelphia, Pa.

The coagulation defect in hemophilia is observed *in vitro* as a prolongation of the whole blood clotting time. Normal blood clots in from 6 to 12 minutes as measured by a modification<sup>15</sup> of the method of Lee and White.<sup>16</sup> The blood of a patient with hemophilia under the same circumstances may not clot for many hours. However, most of the patients in our series have clotting times of from 1 to 2 hours, but in a few the clotting time is in the range of 20 to 40 minutes. Although it has been reported<sup>6</sup> that patients with hemophilia will occasionally exhibit a normal coagulation time, this phenomenon has never been observed in this laboratory.

The coagulation defect in hemophilia has been ascribed by some to an abnormality of the platelets<sup>4</sup> and by others to the presence of an antithrombin.<sup>17</sup> However, hemophilic blood will coagulate promptly upon the addition of thrombin. Tocantins has described the presence of an antithromboplastin in hemophilic blood,<sup>19</sup> while workers in this laboratory believe that there is a deficiency of some factor associated with plasma globulins.<sup>18</sup> Nevertheless, it is generally agreed that fibrinogen, prothrombin, calcium, and the *number* of platelets are all normal in hemophilic blood. Thus, whatever the abnormality, for practical purposes transfusion of whole blood or plasma and certain plasma derivatives will usually bring the blood coagulation time to or near to normal. Hemophiliacs have been observed<sup>20-22</sup> whose coagulation time does not respond as is customary to the administration of blood, plasma or its derivatives. The basis for this failure to react has not been fully elucidated.

Fractionation of blood plasma has led to the identification of the antihemophilic activity with the  $\gamma$ -globulins<sup>16, 23, 24, 25</sup> and particularly with fraction I,<sup>26</sup> according to the nomenclature used by Cohn et al., Fraction III-2 also contains considerable antihemophilic activity. Because of the impracticability at present of the administration of fraction III-2, the fibrinogen fraction I has been chiefly studied *in vivo*<sup>27</sup> and contains antihemophilic activity which has been clearly shown not to be fibrinogen itself.<sup>28, 29</sup>

Occasionally patients are seen who have suffered hemorrhagic episodes but whose coagulation time is only slightly prolonged. It is very difficult either to establish or exclude the diagnosis of hemophilia in these patients, particularly if a family history of the disease is not obtained, as is frequently the case. Certain laboratory procedures may be helpful in this regard. Among these is the well-established reduction in the clotting time of hemophilic blood by the addition of small amounts of normal plasma or its derivatives.<sup>28</sup> The measurement of the recalcification time of plasma centrifuged at different speeds<sup>31</sup> may prove to be a valuable diagnostic test, if substantiated.

#### CLINICAL MANIFESTATIONS OF HEMOPHILIA

It is our purpose to report observations on the clinical manifestations and practical management of forty patients with hemophilia, all of 12 years of age or over, who have been followed in the Thorndike Memorial Laboratory during the last ten years. All were males, the youngest 12, the oldest 58. Eight were in the second

decade of life, 19 in the third, 7 in the fourth, 5 in the fifth, and one in the sixth

Twenty-eight of the 40 (70 per cent of the series) had a family history of hemophilia. Twenty-five had a known member of the family in the same generation with the disease, 14 one generation back, 4 two generations, while none was able to trace the disease further. The lack of a positive family history is in part due to inadequate knowledge on the part of the patients about their families.

There were three patients in whom the family history was known and in whose family no hemophilia had appeared during three previous generations. Whether these instances represent sporadic hemophilia or whether the disease was carried by the female through successive generations without manifestation in a male offspring is not known, but the latter possibility would appear to have more support from the literature.

Spontaneous hemophilia has been reported, the most recent article by Boggs<sup>32</sup> reviews the reported cases and presents six brothers with the disease whose family history gave no evidence of bleeders, although it was known for four generations on the mother's side. Boggs admits that the legitimacy of the mother could be questioned. The statistical likelihood of the occurrence of hemophilia and of carriers in families has been studied by Haldane and Philip<sup>33</sup> who have said: "the daughters of hemophilic men bear equal numbers of normal and hemophilic sons, whilst half the sisters of hemophilic men are heterozygous for hemophilia." The number of individuals in the two sexes in hemophilia was shown to be normal by Macklin.<sup>34</sup>

Most of our cases were of recent European extraction. The family extractions (known in 38 of the families) were: New England 6, Nova Scotia 7, Irish 8, Italian 7, Jewish 3, English 2, Eastern European 5. There were no Orientals or Negroes in the present series, although hemophilia has been reported in both mixed and presumably full-blooded Negroes<sup>35, 36, 37, 38</sup> and six probably authentic cases have been described in native Japanese.<sup>39</sup> Ten of the patients in this series are married with a total of 13 children, 3 males and 10 females. There are no grandchildren.

There were five deaths in the series of forty patients in ten years. Three of these were from conditions quite unrelated to hemophilia, one, age 16, from fractured skull and broken leg following an automobile accident, the second, age 32, from cerebral hemorrhage in terminal malignant hypertension, and the third, age 34, from pulmonary tuberculosis. The fourth, age 21, developed an apparently spontaneous massive hematoma in the left gluteal and thigh muscles with secondary necrosis, slough and sepsis. The fifth death was from rapid submucosal pharyngeal and laryngeal hematoma formation which blocked the airway before help was available.

There were no deaths in this series from acute blood loss, the popularly supposed cause of death in hemophilia. This was in spite of frequent tooth extractions and five relatively serious operative procedures (cf. section on Treatment, Surgery in Hemophilia). Moreover, most of the patients at some time have been admitted to the hospital with a severe hemorrhagic episode.

### *First Hemorrhagic Episode*

In 36 of the patients the first hemorrhagic episode was known and varied in time of onset from the age of one week to 13 years. Three were following circumcision in the first two months (two at the age of one week). Eight others had their first bleeding during the first year of life, two developed an hematoma of the head from known trauma, two bled from cut lips, one had an hemarthrosis of the knee, one hematoma around the knees from crawling, one multiple hematomata, and for one the precise nature of the bleeding had been forgotten. The remaining 25 patients experienced their first hemorrhagic episode during childhood, 19 before five years of age having a variety of hemorrhagic lesions not differing essentially from those to be described for adult life and in most following known trauma.

Excessive bleeding from primary dentition occurred in only one instance of the 22 in whom the history was available, while 13 of 22 had excessive bleeding from secondary dentition. Hemorrhage following the extraction of permanent teeth is much more frequent and will be discussed in a separate section.

### *Hemarthrosis*

Bleeding into joints is the most frequent hemorrhagic episode in adult hemophiliacs. It is usually repeated often so that eventually many joints acquire some degree of permanent damage. Thirty-six of the patients in this series had chronic hemophilic joint disease and almost all of these gave a history of one or more acute hemarthroses. Of the four who exhibited no chronic joint disease and had no history of acute hemarthroses, two had suffered relatively few hemorrhagic episodes of any kind.

Acute hemarthroses and chronic hemophilic joint disease affected the joints in about the same incidence, the knees and elbows being by far the most frequently involved. The ankles, hips and shoulders were affected much less frequently, and the wrists, fingers and toes only occasionally.

Acute hemarthroses frequently occur without known external trauma, although joints, especially those bearing weight, are subject to the continual trauma of movement. The hemarthrosis is heralded by stiffness that soon becomes painful on movement of the joint. It is followed within a few hours by swelling which gradually distends the joint capsule causing severe pain even at rest, being greatly aggravated by motion. Tenderness is exquisite and limited, at least at first, as is the swelling, to the areas where the joint surface is relatively superficial. For example, in the elbows, the areas lateral to the olecranon are swollen, tense and exquisitely tender. The blood may break through the tense capsule and be released into the neighboring tissues, temporarily relieving somewhat the pain and tenderness of the hemarthrosis. When this occurs the blood may dissect superficially giving the typical discoloration of an ecchymosis. However, usually the blood remains confined to the joint and discoloration is then not observed. It is because of this lack of discoloration around a joint that an acute hemarthrosis is sometimes mistaken for other forms of acute arthritis. During the acute phase the joint is usually held in the position of greatest relaxation, the knees and elbows, for

example, in partial flexion, and any attempt to change the position is attended by severe pain

Usually in from four to six days recovery from the acute phase begins. Pain and tenderness subside a little and the previously tense stretched skin over the joint shows a fine wrinkling. Recovery usually then proceeds rapidly but may require two or three weeks before it is maximal. Residual limitation of motion is common and may become permanent, particularly if the joint has been the object of frequent previous attacks.

Acute hemarthrosis has been mistaken for acute rheumatic fever, rheumatoid, gonococcal and other types of arthritis, but may be readily differentiated if hemophilia is considered.

### *Chronic Hemophilic Joint Disease*

Following repeated acute hemarthroses a chronic and often deforming joint disturbance occurs. This is not to be thought of as a chronic hemarthrosis, but rather as the result of frequent irritation to the joint leading to roughening of the joint surfaces and fibrosis together with both areas of bone reabsorption and new bone formation. The description of both acute and chronic hemophilic joint disease by König<sup>40</sup> is the classical one, but a considerable body of literature has been published on the subject. Caffey and Schlesinger<sup>41</sup> point out that coxa plana resembling Perthes disease may be the result of joint hemorrhage and further that epiphyseal overgrowth and precocious ossification may be demonstrated by x-ray. Fonio,<sup>42</sup> Newcomer,<sup>43</sup> Lamv,<sup>44</sup> Keifer and Myers,<sup>45</sup> and MacDonald and Lozner,<sup>46</sup> have discussed the clinical and x-ray findings. The latter two papers are based on patients included in the series reported here.

In spite of active preventive measures, such chronically affected joints usually show some limitation of motion and may eventually become ankylosed. The joints are enlarged, the characteristic fusiform appearance being accentuated by atrophy of muscles on either side of the joint. Tenderness and pain on movement are not characteristic of chronic hemophilic arthritis, in fact, if either is present, recent active bleeding has probably occurred.

In only two of this series of forty hemophiliacs was there no evidence of chronic hemophilic arthritis. One would, in fact, hesitate to make the diagnosis of hemophilia without the presence of joint deformity unless the diagnosis could be otherwise conclusively established.

Arising usually after extensive bleeding into and around a joint, Volkmann's contracture sometimes becomes a serious deformity, greatly limiting usefulness of the extremity.<sup>47-50</sup>

### *Hemorrhage into the Skin, Subcutaneous Tissue and Muscles*

Purpura is not the characteristic phenomenon in hemophilia that it is in purpura hemorrhagica. Ecchymosis and hematoma when they occur usually follow known trauma rather than appear spontaneously as they do in purpura hemorrhagica. Ecchymoses seldom spread extensively but hematomata into subcutaneous tissue often spread until they are limited by fascial attachments.

Bleeding into muscle almost always follows severe trauma and may spread rapidly, usually into the subcutaneous tissue and along fascial planes. Subcutaneous and intramuscular hematomata are usually much larger than superficial examination would suggest. Shock from blood loss is not uncommon, and anemia, icterus (with an increased indirect serum van den Bergh reaction), reticulocytosis and urobilinogenuria follow. Hemorrhage into the gluteal region with spread into the thigh is one of the most common and because of the amount of available space may be extensive and lead to early shock.

### *Hemophilic Pseudo Tumor*

Occasionally, bleeding into or around bone tissue may be extensive and persistent enough to interfere with the blood supply and cause reabsorption of bone. This is observed chiefly in the hands or feet and the part may be converted in the course of weeks or months into a swollen, tense sac of old blood and destroyed tissue. X-ray examination is usually misinterpreted as sarcoma because of the soft tissue swelling and bone absorption. Firor and Woodhall<sup>51</sup> reviewed the literature on this subject and reported a case of their own, a 15-year old boy who developed a gradually progressive swelling of the right thumb over 18 months following injury. X-ray revealed absorption of bone and a diagnosis of bone sarcoma was made. Successful amputation was done with the aid of an electric cautery. A 16-year old boy in our series had a similar occurrence which developed over the course of almost a year and involved the left foot from the mid-tarsus distally. The metatarsal bones were almost completely resorbed and an x-ray diagnosis of sarcoma was made. Surgical amputation was done with great care and with a good result.

In addition to the pseudo tumor of the distal end of the extremities, other changes such as calcification in a subperiosteal hematoma have been described as sarcoma. In these instances there may be reabsorption of bone also, making the resemblance to sarcoma of bone the more real. Starker<sup>52</sup> discussed subperiosteal hematoma in hemophilia and Echtermacht<sup>53</sup> described a 13-year old boy with a huge hematoma associated with the left tibia that was mistaken at first for tumor. The patient died three days after amputation.

### *Hematuria*

Attacks of hematuria are one of the most frequent hemorrhagic episodes in hemophilia, in fact almost 90 per cent of the patients in our series have had one or more episodes. Recurrent attacks are very common. The attacks are usually spontaneous but occasionally follow direct trauma to the kidney region. In one instance an attack was apparently induced by a prolonged train ride, the patient being frequently jarred while sitting up in the coach.

The onset of hematuria is usually symptomless except for the appearance of red urine. Occasionally pain may herald the beginning of the attack or may occur at any time during the course, but it is most common toward the end. The pain is due to the passage of clots, and its location and character depend upon the site of

clot formation. Generally the pain is typical renal colic indicating that the bleeding is from the kidney or pelvis. Following a bout of pain a clot is sometimes passed during micturition and is usually accompanied by severe dysuria.

An attack of hematuria may last a day or so, or may be prolonged for several weeks, no known factor or form of treatment apparently affecting the duration.

Initial or terminal hematuria are seen occasionally as a complication of disease in the anterior or posterior urethra. The spontaneous hematuria of hemophilia may be confused with any one of the other causes of the symptom for which investigation should be made, particularly if the hematuria frequently recurs. Weil<sup>54</sup> believes that hematuria in hemophilia is in most instances caused by the presence of stone. The frequent occurrence of hematuria in the disease makes this appear unlikely.

Although the urine may become quite dark, the actual loss of blood during an attack of hematuria is usually not enough to alter significantly the blood hemoglobin content.

#### *Pharyngeal and Laryngeal Hematomata*

Hematoma formation beneath the mucosa of the pharynx and larynx is one of the few emergencies in hemophilia because of the rapid occurrence in some of the few emergencies in hemophilia because of the rapid occurrence in some of airway obstruction. Fortunately this does not occur very often, although one of the five deaths in this series was from this cause. Baird and Fox<sup>55</sup> found seven instances of this complication reported, in four of whom tracheotomy was not performed and who recovered, while three died following this operation. In their own case tracheotomy was done with recovery.

The patient usually complains first of sore throat, loss of voice, or both. With either of these symptoms careful examination of the larynx and pharynx must be made at once. Sometimes the bleeding begins as an obvious swelling on the posterior pharyngeal wall, but more commonly it cannot be seen except by indirect laryngoscopy. In the latter case the hemorrhage frequently discolors the mucous membrane over the arytenoids and spreads down the laryngeal wall to the false and true cords. Fortunately, obstructive symptoms have not occurred in most of our patients, but when they do they may either appear within a few hours or be delayed for a day or so.

It has been our custom to hospitalize each of these patients at once and to keep a tracheotomy kit readily available (see section on Treatment).

Although most instances of pharyngeal and laryngeal hematoma formation appear to be spontaneous, it may follow overvigorous use of the voice, against which hemophiliacs should be cautioned.

#### *Pulmonary and Pleural Complications*

Pulmonary and pleural bleeding are uncommon complications in hemophilia, although mediastinal and pleural shadows appearing in roentgenograms, presumably from fresh or old hematoma, have been reported.<sup>56</sup> Massive hemothorax and hemoptysis are rare.<sup>57</sup> These complications were not observed in our patients.

*The Acute Abdomen in Hemophilia*

Not only are the usual acute abdominal conditions a problem in hemophilia because of the high operative mortality,<sup>15</sup> but in addition, certain forms of intra abdominal and retroperitoneal hemorrhage so resemble acute surgical emergencies that the greatest diagnostic acumen and surgical caution must be exercised to avoid a fatal result

All the common acute abdominal conditions such as acute appendicitis, acute cholecystitis, perforated peptic ulcer, acute pancreatitis, etc., may, of course, appear in hemophiliacs. Although it is difficult to ascertain the degree, bleeding from or into the damaged tissue may complicate these acute abdominal conditions by increasing the symptoms and delaying healing. Where infection is present it may travel with the bleeding, and in this way spread much farther than it otherwise would. Therapeutic procedures will be discussed in the section on treatment.

Hemophiliacs, in addition, suffer a variety of purely hemorrhagic intra abdominal episodes which both closely mimic and are more frequent than the usual acute abdominal emergencies. In many instances such hemorrhagic episodes are difficult, if not impossible, to differentiate from the common forms of the acute abdomen. Sometimes the course of the illness establishes whether it is purely hemorrhagic or not, but all too frequently the differentiation is obscure and it is extremely difficult to decide not to perform a highly dangerous operation.

Severe upper abdominal pain, usually cramp-like, but sometimes steady and resembling a penetrating or even perforated ulcer, is occasionally seen. The onset is usually progressive over several hours with pain reaching great severity and usually associated with nausea and vomiting. The abdomen may become distended, with upper abdominal tenderness or even generalized tenderness and a board like rigidity. Moderate leukocytosis is usual. The acute condition usually lasts from one to two days and then gradually subsides over a period of several days or occasionally recurs. To place the bleeding accurately in these episodes is usually difficult. In some instances, intraperitoneal bleeding becomes evident by the appearance of free fluid in the peritoneal cavity, together with signs of acute blood loss. A positive benzidine or guaiac reaction in the stool a day or so after the beginning of the episode indicates bleeding into the gastro-intestinal tract, which may be due only to mucous membrane bleeding from persistent retching and vomiting. Massive melena may sometimes complicate this upper abdominal bleeding syndrome, but hematemesis is rare.

Pain in the midabdomen, usually cramplike, and resembling small bowel obstruction is a distressing although uncommon complication in hemophilia and is probably due in most instances to bleeding into the bowel wall, the mesentery, or both, and sometimes associated with intra-abdominal bleeding. Moderate distention and vomiting are the rule and are due to paralytic ileus.

Low abdominal pain is the commonest of the abdominal emergencies in hemophilia. Two apparently unrelated forms of bleeding may occur into the colon wall or the mesocolon, or into or around the ileopsoas muscle. In the first instance, bleeding into the colonic wall or mesentery, the signs are usually those of partial

bowel obstruction vomiting, cramplike abdominal pain, and abdominal distention. A tender, low intra-abdominal hematoma usually forms after a day or so, and finally after several days it may discharge its contents into the bowel with the sudden appearance of melena. Patients exhibiting this condition have been described by Vance<sup>59</sup> and Platou and Platou.<sup>60</sup>

Retroperitoneal bleeding is more common in the low abdominal syndrome than that associated with the colon, and is usually due in these instances to bleeding into or around the ileopsoas muscle. The fact that 15 of our 40 patients had at least one episode of ileopsoas hemorrhage illustrates its frequency and importance as a complication of hemophilia. The syndrome has been described by Birch,<sup>61</sup> Günther,<sup>62</sup> and Fallroth.<sup>63</sup> When on the right side, the ileopsoas hemorrhage resembles acute appendicitis, although the pain seldom begins in the epigastrium. At first the pain is mild but usually in the course of hours becomes severe. Tenderness to palpation and percussion are often exquisite over McBurney's point and rebound tenderness is the rule. There may also be tenderness on rectal examination on the affected side. Leukocytosis is almost always present but usually is moderate. The blood loss is seldom sufficient to produce anemia or signs of acute blood loss. A mass due to a retroperitoneal hematoma often appears within 24 to 48 hours and may be mistaken for an appendiceal abscess, even though the latter seldom appears this early after the onset of the symptoms. Occasionally the hematoma spreads distally down the ileopsoas muscle and may become palpable at Poupart's ligament or even in the femoral canal. When this occurs, differentiation from acute appendicitis becomes easier.

Further aid in differentiating ileopsoas hemorrhage from other intra-abdominal conditions is the distressing complication of partial or complete involvement of the femoral nerve. This usually begins with pain on the anterior surface of the thigh and may be observed soon after the onset of the bleeding. A positive 'psoas sign' may be seen at this time and the hip is usually held in partial flexion. Paresis may be seen at this time and the hip is usually held in partial flexion. Paresis and usually partial or complete anesthesia often follows within two or three days and weakness or paralysis of the thigh extensors with subsequent muscular atrophy follows. As mentioned above, the acute episode lasts as a rule for but a few days, but the mass when present may disappear slowly or even may remain permanently. Likewise, the femoral nerve damage is slow to heal and hypesthesia, muscular weakness and atrophy may be permanent.

#### *Neurologic Complications in Hemophilia*

Spontaneous intracranial hemorrhage is rare in hemophilia<sup>64</sup> in contradistinction to purpura hemorrhagica in which it is the most common cause of death.<sup>9</sup> Bleeding into or around the spinal cord is likewise seldom seen in hemophilia although retroperitoneal hemorrhage sometimes impinges upon a nerve root as it emerges from the spine producing typical unilateral radicular pain.

Peripheral nerve lesions of varying severity and location are very common and usually complicate hemorrhage into a joint or muscle which is in close proximity to the nerve. Thus, the ulnar and superficial peroneal nerves are frequently damaged

in this way Retroperitoneal ileopsoas hemorrhage affecting the femoral nerve is discussed above in the section on the acute abdomen A very complete review of the neurologic complications of hemophilia is to be found in an article by Aggeler and Lucia<sup>65</sup>

### THERAPY IN HEMOPHILIA

In addition to the many manifestations of hemorrhage itself, bleeding in hemophilia may complicate other coexistent diseases The treatment of these primarily nonhemorrhagic conditions may be further complicated by secondary hemorrhage Treatment is directed both to rectifying the diminished blood coagulability locally and systemically, as well as to whatever nonhemorrhagic condition may be present

1 *Blood coagulants* For generations man has been searching for methods to stop bleeding and the number of remedies, both household and medical, attest both the frequency of the problem and the general inefficacy of the methods of hemostasis In an effort to halt the excessive bleeding in hemophilia, a great many remedies have been described, most being for parenteral administration<sup>66-79</sup> We have had little or no experience with most of these therapeutic agents, many of which have been proven ineffective Since Weil<sup>80</sup> in 1905, found that the therapeutic effect of blood transfusions in hemophilia was due to bringing the coagulation time to or near normal, this form of therapy has not only passed the test of time,<sup>81 82</sup> but also is the most physiologic of all the parenteral remedies tried However, even when the coagulation time is brought to normal with blood transfusions the bleeding may continue

Since the antihemophilic activity of both blood and plasma gradually disappears when preserved even at refrigerator temperatures<sup>83</sup> it has been our policy to use human whole blood or plasma not over 24 hours old unless, in the case of plasma, it has been separated soon after phlebotomy and preserved in the frozen state Lyophilized plasma has been shown to be active,<sup>84</sup> but for optimum effectiveness it can not always be depended upon, as several days often elapse between the drawing of the blood and its processing

In the case of acute blood loss of significant proportions either externally or into the tissues, fresh whole blood is the choice, for it not only provides antihemophilic activity but replaces the loss in both red cell and plasma volume Plasma, fresh or frozen, is simpler because cross-matching is not required and it is as rich as whole blood in antihemophilic activity It has been our custom to administer whole blood in the amounts dictated by the severity of the blood loss If whole blood is not necessary, plasma is given in 100 cc to 250 cc quantities for its antihemophilic properties The reduction in coagulation time is usually to or near to normal This effect persists for 6 to 12 hours at the minimum and then the clotting time gradually rises to its preinjection level in the course of another 6 to 12 hours<sup>27</sup> (fig 1) Thus, for continued effect on the coagulation time of the hemophilic patient, blood or its products should be given once or perhaps twice daily during the period of active bleeding

A hemophilic may vary considerably from time to time in his response to antihemophilic material of known potency It is important to determine the coagula-

tion time shortly after the administration of the antihemophilic agent, e g,  $\frac{1}{2}$  hour, and again at a 6- to 8-hour interval, in order to follow the extent and duration of the effect. If the coagulation time does not reach or remain at or near normal the administration should be repeated.

As described above in the section on the coagulation defect in hemophilia, blood plasma fractionation has led to the production of a preparation of human fibrinogen which contains antihemophilic activity and which can be given intravenously to patients with hemophilia.<sup>27</sup> In the dosage recommended there have been no significant reactions observed, and no reported cases of serum jaundice have occurred. \*In addition to absence of icterogenic properties, the material has the ad-

FIG. 1

advantages over whole blood and blood plasma that very small amounts need be administered for maximum effect and that it can be easily and quickly given. There is a great deal of variability in the antihemophilic activity of Fraction I as now available, and there are, in fact, instances when fresh whole blood is more effective in reducing the coagulation time. Thus, the material is in no sense a cure for hemophilia, but its production is a step toward finding a potent therapeutic substance and hopefully a prophylactic material which could be given in hemophilia much as insulin is to a diabetic. For many years such a preparation has been the dream of both hemophiliacs and investigators. In his lectures to students, Dr. Minor has often referred to this goal. At present the limitations in the avail-

\* Since this paper has been submitted for publication two cases of hepatitis probably transmitted with the administration of Fraction I have been observed.

able quantity of Fraction I and problems of stability and route of injection have prevented its use as a prophylactic. Nevertheless, attempts at maintenance of a reduced blood coagulation time have been made by injecting fresh<sup>85</sup> or lyophilized<sup>86</sup> plasma once a week or more often. Significant prolongation of the interval between hemorrhage has been obtained in this way.

The refractory state to blood and its derivatives referred to in the introduction follows, in some instances, the repeated administration of blood, plasma, or the antihemophilic globulin fraction, and arises during or promptly after an hemorrhagic episode, although occasionally it is spontaneous.\* The exact nature of this refractory state is still obscure, but recent work has suggested that there may be a production of antibodies to the antihemophilic substance.<sup>81</sup> This observation has yet to be confirmed.

2. *Rest and exercise* Although strict precautions must be taken by the hemophilic against trauma, this does not mean that he should live a sheltered, inactive life. Heavy manual labor, prolonged fatiguing exercise, the more vigorous sports, and other activities that require severe physical exertion should not be attempted, however, moderate activity should be encouraged depending upon the physical capabilities of the individual, for it not only gives the individual a sense of equality with his associates, but also helps to maintain muscle tone and joint mobility. It is our impression that the decrease in muscle size and tone which occurs with immobilization and disuse<sup>88</sup> may be an important factor in initiating hemorrhage into the muscles and neighboring tissues. Although it is difficult to evaluate because of the possible cyclic frequency of hemorrhages, bed rest with its attendant inactivity appears to us to be an important predisposing factor to hemorrhage. Thus, a hemophilic confined to bed for an acute hemarthrosis, for example, not uncommonly develops hemorrhage in other parts of the body. Convalescent patients are therefore encouraged to take moderate exercise. The aid of an expert physical therapist should be available for directing exercise, both while the patient is in bed and during ambulatory convalescence.

3. *Use of sedatives and analgesics* The fact that internal hemorrhage in hemophilia is regularly accompanied by severe pain which may last for several days or more, and that repeated episodes may be expected throughout the patient's life makes the choice and use of analgesics difficult and of prime importance. The use of morphine is sometimes necessary, but should be avoided if possible. If it is required, the drug should be administered for as short a period as possible because of the danger of dependence and habituation. Meperidine hydrochloride (demerol hydrochloride), also contributing to addiction,<sup>87</sup> has been useful in our hands, but occasions arise in which only morphine is effective. When it is decided to administer these or similar analgesics, maximum effective doses should be used to control the pain.

Aspirin, often fortified with codeine, is often effective for less severe pain, but in the case of codeine too, care against habituation must be taken since moderate pain may be prolonged for weeks, as for example, following an hemarthrosis. Hypnosis with barbiturates may make pain bearable, especially at night.

\* Presently available evidence suggests that this refractory state may occur more frequently following the administration of the antihemophilic globulin fraction than following the administration of blood or blood plasma. The therapeutic use of the antihemophilic globulin fraction cannot be advised therefore until further studies have eliminated this hazard.

4 *Local treatment of external bleeding* Aside from the parenteral administration of blood and its derivatives to reduce the blood coagulation time, many substances have been produced for use locally at the site of bleeding. Some of these preparations are very poor coagulants, and most of those that are effective at all exert their effect as a thromboplastin. That is, they hasten the coagulation of the blood by action with prothrombin and calcium, resulting in the production of thrombin which converts fibrinogen to fibrin. We prefer thrombin as a coagulant because it directly converts the fibrinogen to form a fibrin clot. We have had excellent results with a thrombin prepared from animal blood<sup>88</sup> <sup>89</sup> Thrombin may also be prepared from human blood<sup>89</sup> and has recently been produced on a large scale as a by-product of the preparation of human serum albumin from plasma.<sup>90</sup>

No matter what local coagulant is chosen, adherence should be made to certain general principles. The wound should be cleaned with as little trauma as possible, debris and clots of blood being gently removed. Approximation of the edges may be desired but should not be made with sutures unless absolutely necessary, as each needle hole is another source of bleeding. Thrombin is applied directly to the site of bleeding and is held there by appropriate pressure dressings. It is important to emphasize that the thrombin must be applied directly to the source of bleeding, if not, it will merely form a blood clot in the wound, keeping it open and preventing approximation of the edges, effective hemostasis, and healing. The two principles of treating superficial wounds in hemophilia, then, are first that a known active coagulant be applied to the bleeding surface, and second, that it be maintained there with some form of pressure dressing.

Some of the earliest surgical experiences with hemophiliacs were with the use of cautery, both chemical and thermal. Poland<sup>86</sup> in 1850 described a patient in whom pure nitric acid stopped bleeding from a traumatic lip lesion on two occasions. Ericksen<sup>91</sup> in 1856 tells of a 34-year old male who developed an hematoma extending from the ankle to the popliteal space. Following incision, bleeding areas were touched with cautery with cessation of bleeding. Gangrene developed, however, and following amputation by ligature and cautery, the patient died.

Although cautery may temporarily stop bleeding, its use is not advised since surrounding tissues are usually destroyed or damaged, leading to a secondary area of slough and an enlarged area of bleeding. Thus, a ten year old boy seen by one of us had been treated by cautery with dichromate for a clean tongue cut. The bleeding stopped, only to recur two days later with renewed vigor from a larger wound, this time being stopped only by the application of thrombin on a gauze pack held in place by sponge forceps.

5 *Surgery in Hemophilia* Operative surgery in patients with hemophilia is hazardous and attended by a high mortality.<sup>92</sup> Friedrich<sup>88</sup> estimated a 35 per cent mortality following major operations, and his estimate is probably a conservative one. The operative treatment of specific conditions will be discussed in subsequent sections.

Medical literature concerning hemophilia is replete with reports of various surgical procedures which have been attempted. In most instances some form of local or parenteral coagulation therapy was used, often in addition to blood trans-

\* Hemostatic Globulin (Dried) furnished by Lederle Laboratories Division, American Cyanamid Company, Pearl River, New York.

fusions Many of these were listed above (Section 1 Blood Coagulants ) but are not discussed because of their large number and variety and the lack of precise observations of their effectiveness Some have been shown to be ineffective

In spite of the high mortality rate, operations, sometimes of considerable magnitude, have been done Among those reported, some of which were successful but many not, are appendectomy,<sup>93</sup> <sup>94</sup> gastro-enterostomy,<sup>96</sup> partial gastrectomy,<sup>9</sup> arthroplasty,<sup>98</sup> <sup>99</sup> eye enucleation,<sup>100</sup> prostatectomy,<sup>101</sup> nephrectomy,<sup>102</sup> mastectomy,<sup>50</sup> and various amputations<sup>103</sup>

If an operation is decided upon, the free use of preoperative and postoperative blood transfusions and, when possible, the local application of thrombin (Section 4) are the only important additions to careful surgical technics Specific surgical problems will be discussed as they occur in the following sections

6 *Treatment of acute hemarthrosis* When an acute hemarthrosis occurs in the lower extremity, bed rest is necessary, otherwise, the patient may be ambulatory, with a sling or other support if the pain permits Ice bags to the part give some symptomatic relief Pain is usually extreme and analgesia is indicated Compression bandages applied before much swelling has occurred have been found useful by some Aspiration of the fluid blood in the joint is not recommended because of the danger of infection and, moreover, in our hands has failed to shorten convalescence significantly Following aspiration of blood the joint pain is usually greatly relieved but returns again in a very few hours Thrombin preparations (sterile, human) may be injected into an acute hemarthrosis, but this therapy has not yet proven to be of value

It is usually not possible to place the affected joint in optimum functional position during the acute phase nor do we consider it necessary since as soon as signs of reabsorption of blood appear, cautious active movement up to the point of pain may be begun and gradually increased, usually until the former range of movement is attained As convalescence progresses and danger from renewed bleeding diminishes, physical therapy is in the form of radiant heat, and whirlpool baths hasten recovery of function Early active movement and physical therapy are the best preventatives of ankylosis

7 *Treatment of Chronic Hemophilic Arthritis* Treatment of arthrosed or otherwise deformed joints is largely orthopedic and must be undertaken with great care so that hemorrhage is not induced either into the affected joint or at points of pressure The use of plaster casts which are gradually wedged to the desired position has often been successful The amount and frequency of the wedging is distinctly less than in nonhemophilic patients, each spreading of the cast being up to the point of first pain Simple Buck's extension is also frequently useful but the same precautions must be observed

Arthroplasty, like other operative procedures in hemophilia, must be seldom undertaken and then only with full knowledge of the mortality as well as the likelihood of a poor result from bleeding into and around the operative site If operation is decided upon, the suggestions listed under Surgical Treatment may be helpful in avoiding complications

However, in spite of these measures, the joints of patients with hemophilia may

become partially or completely ankylosed with deforming muscle contractures and atrophy. When this happens in the legs, symptomatic calluses usually develop on the feet. Softening and removing these calluses provides only temporary relief, but more prolonged help can be obtained with corrective shoes. Patients with hemophilia can use aids to walking without difficulty, such as canes and crutches, and we have one individual in our series who is successfully wearing a prosthetic for a surgically amputated foot.

8 *Treatment of subcutaneous and intramuscular bleeding, and of pseudo tumor.* Bed rest with immobilization of the part is usually automatically resorted to by a patient with a large hematoma of the soft tissues. Ice bags, as in acute hemarthrosis, provide some relief, and analgesia is often required. Firm pressure from an elastic bandage over the entire area and especially over the bleeding point, if known, may reduce the bleeding. It cannot be overemphasized that a large amount of blood may be lost into the soft tissues without producing what would seem to be commensurate swelling. A continual watch of pulse, blood pressure, and hematocrit must be made so that shock does not occur. Blood transfusions not only supply the antihemophilic factor but also replace blood lost.

Great care must be taken to prevent ulceration of the skin over the hematoma as infection and renewed bleeding may become major therapeutic problems.<sup>104, 105</sup>

Hemophilic pseudo tumor, with necrosis and reabsorption of bone, as well as soft tissues, is a potential hazard when fully developed because of its awkwardness and susceptibility to infection. Amputations have been done for this condition. If undertaken, extreme care must be exerted to see that the blood coagulation time is as close to normal as may be obtained and that the surgery induces the least possible trauma. Thrombin should be placed between the stump and its covering.

9 *Treatment of peripheral nerve lesions.* Little further than the treatment outlined in section 7 and 8 can be done to treat the neuritis that not uncommonly develops during the active phase of intramuscular or subcutaneous hemorrhage. Complete regeneration of nerves may be expected in the course of time in many instances while some will be left with residual nerve damage. Physical therapy to maintain muscle tone and prevent contracture and bony ankylosis of joints is indicated. When splints are applied to avoid contracture, they should be bivalved so that physical therapy may be instituted.

10 *Treatment of hematuria and certain urologic complications.* Bleeding from the genito urinary tract is usually renal in origin and is frequently resistant to treatment, continuing in spite of the repeated administration of fresh blood or its derivatives and satisfactory reduction of the blood coagulation time. Absolute bed rest in the supine position may be tried but in our hands has been largely ineffectual. In occasional patients there may be prompt cessation of bleeding following some form of therapy, but generally after a variable period it ceases spontaneously. Except for the occasional development of a mild blood loss anemia there have been no ill effects from continued hematuria. The ureteral passage of blood clots, particularly frequent when bleeding is decreasing, usually causes severe renal colic and may require the administration of morphine or demerol for relief.

As mentioned above, search should be made, if suspected, for stone tuberculosis,

malignancy, or other causes of hematuria, particularly if repeated episodes of bleeding occur. Cystoscopy may be performed in hemophilia if necessary and if carefully done, but ureteral catheterization or retrograde pyelography may induce submucosal ureteral bleeding and probably should not be performed.

Operative intervention in urologic problems in hemophilia is extremely serious. Barney<sup>108</sup> in 1933 described a case in which following a necessary suprapubic cystotomy, failure to control the bleeding resulted in death. Mertz and Meiks<sup>109</sup> reported a patient who died eight days after a nephrectomy for hydronephrosis in spite of repeated transfusions. Hinman,<sup>101</sup> however, successfully removed a prostate in a 66-year old hemophiliac.

*11 Care of the teeth, dental extraction.* Dental prophylaxis is of paramount importance in the care of the hemophiliac. It is to the advantage of the patient that he be seen regularly and often by his dentist and that prophylaxis and necessary repair be performed at an early date. Cavities can be filled without fear of hemorrhage although care should be taken to avoid undue trauma to the gums.

However, frequently, due to the failure of the patient to seek dental care or reluctance of the dentist to perform the indicated procedures, extraction is necessary. In conjunction with the Department of Oral Surgery, Boston City Hospital,\* the method described below has been successfully employed many times in the last five years.

The plan involves reduction in blood coagulation time by parenteral fresh blood or suitable derivatives, and the application of thrombin with pressure to the socket provided by a partial or complete denture.<sup>12 107 108</sup> By combining these two techniques we have been able to perform dental extractions in hemophiliacs with a progressive reduction in the postoperative bleeding so that at present it is minimal.

Before the extraction is performed an impression is taken of the jaw from which the tooth is to be extracted. From this a well-fitting partial or complete denture is made. Its essential features are a labial flange extending from the main body of the denture across the socket from which the tooth is to be removed, and two wire clasps, one on either side of the denture, that serve to secure it firmly in position. Approximately a week prior to the operation, a thin, tightly fitting band of rubber (orthodontia band) is placed about the neck of the tooth to be extracted. During the succeeding several days this band progresses along the tooth root, partially separating it from the adjacent tissues. At times the band will progress rapidly along the root so that it may be necessary to use two or three such bands in order to keep the soft tissues from reapproximating to the tooth after the band has passed.

An hour or so before the actual extraction the patient is given an amount of antihemophilic globulin sufficient to reduce his coagulation time to 15 minutes, or lower if possible. In the event that this material is not available, fresh whole blood, frozen plasma, or its equivalents in antihemophilic activity, may be used. Similar amounts of antihemophilic globulin are routinely administered on the first, second and third postoperative days.

\* The principles and technic employed are largely the result of the enthusiastic work of Dr. Stephen P. Mallett, Oral Surgeon in-Chief, and his staff, particularly Dr. Phillip H. White. We are indebted to them for the details of this presentation which will subsequently be reported in full.

In the majority of our cases, novocaine has been used as an anesthetic although nitrous oxide-oxygen inhalation anesthesia may be safely employed. In extractions of the maxillary teeth it has been the practice of the operator to infiltrate with a fine gage needle the tissues at the free cuff margin of the gingivae rather than using the more conventional type of infiltration. By so doing, the tissues traumatized are localized in one area, over which the mechanical pressure of the denture will be applied. Mandibular block injections are usually necessary for the removal of teeth from the lower jaw, although in this procedure there is danger of causing pharyngeal hematoma.

An attempt should be made to extract the tooth with as little trauma as possible. On occasions, however, small lacerations of the gums have occurred and the socket septa have been removed without increased bleeding.

After the tooth has been removed the socket may be gently sponged and cleaned. Using dried thrombin, an empty novocaine capsule is then firmly packed into the defect and buttressed with a more solid mechanical filler. An oxidized cellulose preparation\* has proven to be very satisfactory for this purpose. No attempt is made to suture the gum margins. The denture is then inserted into position, care being taken to see that the flange fits firmly over the socket.

In the majority of instances, there will be insignificant postoperative bleeding. If such is the case the denture is not removed for approximately a week. At the end of this time it may be taken out for a short trial period. If oozing still continues, a small amount of dried thrombin is applied to the bleeding surface and the denture reinserted. This is repeated at one- or two-day intervals until complete hemostasis has been obtained. If more vigorous bleeding occurs, the denture may be easily removed at any time, the socket cleaned of old clots and repacked, and the denture reinserted.

It is of utmost importance to have a well-fitting denture. It is uncomfortable to the patient if it fits too tightly and local pressure necrosis may occur. On the other hand, if it fits too loosely sufficient mechanical pressure will not be applied in the appropriate area or the movements of the denture may dislodge the clot and hemostasis will not be obtained. By adding flanges as needed to the original denture it may be used for more than one extraction. However, a new denture has to be made from time to time to compensate for the shrinkage of the soft tissues and resorption of the underlying bone. The unpleasant taste that usually occurs after two or three days' wearing of the denture may be partially alleviated with simple mouth washes.

During the period that the denture is being worn, the patients are permitted to be up and about the ward and to engage in their usual activities. They are able to eat and sleep regularly. Conventional partial or complete dentures can be worn by the hemophiliac without difficulty.

12. *Treatment of pharyngeal and laryngeal hematoma.* The potential seriousness of pharyngeal or laryngeal hematoma lies in its occasional propensity rapidly to occlude the airway. For this reason, if suspected, the diagnosis must be confirmed by a competent laryngoscopist and, if confirmed, the patient should be hospitalized.

\* Oxy-cel provided by Parke Davis & Company, Detroit, Michigan.

so that proper supervision is available. A tracheotomy kit is kept near at hand. The diet should be soft or liquid and absolute voice rest enforced. Administration of fresh blood or its derivatives to reduce the blood coagulation time is essential. Generally within 24 hours the swelling begins to recede and convalescence is then rapid and uneventful. If obstruction of the airway becomes imminent, tracheotomy should be done, with the most careful surgical hemostasis and with the liberal use of blood or its derivatives.

13 *Abdominal surgery* In the discussion above concerning The Acute Abdomen in Hemophilia the difficulty was emphasized of differentiating either intra-abdominal or retroperitoneal hemorrhage from the usual acute abdominal conditions. In this regard, Traum<sup>7</sup> reported a patient who was operated upon with a mistaken diagnosis of peritonitis from a ruptured appendix. An hematoma the size of a child's head was found around the right kidney which was evacuated and packed. The patient subsequently died. Scherk<sup>109</sup> has discussed the differential diagnosis of abdominal symptoms in hemophilia and described a 47-year old hemophiliac in whom a diagnosis of acute appendicitis was made. He was treated without operation in spite of the development of a sausage-shaped tumor in the right lower quadrant which disappeared in eight days. A gangrenous appendix, however, was successfully removed by Prima<sup>94</sup> complicated by a fist-sized hematoma in the wound. Cioran<sup>95</sup> likewise reported the removal of a perforated gangrenous appendix with a good result.

It is impossible to be didactic concerning operative intervention on patients with hemophilia in whom an acute abdomen is suspected. Two important facts may be reiterated, however. Intra-abdominal or retroperitoneal bleeding is far more common in hemophiliacs than are the usual abdominal emergencies. Secondly, major surgery has a very high mortality rate in hemophilia. With these facts in mind an unnecessary operation usually may be avoided. A case in point is that of Platou and Platou<sup>60</sup> concerning an eight-year old hemophiliac who was very ill with signs of intestinal obstruction. He improved following the institution of continuous gastric aspiration. Blood transfusions were administered and operation was delayed from day to day and finally avoided. A diagnosis of bleeding into the bowel wall was made. In our experience this set of circumstances has occurred a number of times and operation has not yet been necessary. Likewise, in patients with pain in the right lower quadrant resembling appendicitis, operation has not been done although their number has been large. An ileopsoas hemorrhage was suspected in each. In view of the work of Crile<sup>110</sup> with the use of massive doses of penicillin in peritonitis resulting from appendicitis, the danger of not removing an acutely inflamed appendix may not be as great as it was formerly considered to be. It is probable that occasionally an acute appendix will be missed by this conservative treatment, but again, the operative risk may be as great or greater than that of an unoperated, acutely inflamed appendix.

14 *Social, economic and psychiatric implications* An hereditary disease with an outlook of life-long partial disability inevitably brings with it a multitude of social, economic and psychiatric problems. It is the physician's duty not only to care for

the hemorrhagic episodes, but, in addition, to consider and advise on such matters as vocation, marriage and children

Rightfully, preventive therapy must begin in childhood as soon as the diagnosis of hemophilia is established. The nature of the disease must be clearly explained to the parents so that they will not only endeavor to prevent hemorrhages but will so orient, care for, and instruct the child that he will grow into as useful and productive a citizen as possible, for only in this way will he be well adjusted, and thus happy. More than most children he must be taught independence and self-reliance and must not depend too much upon his parents. This is often difficult for the rest of the family for the hemophiliac is, of course, subject to frequent bouts of pain which automatically make him the center of attention.

Early in life a vocation must be carefully planned. Too often hemophiliacs grow to adult life with little formal schooling because of frequent illness. Vocational training is likewise scanty so that they are capable only of manual labor for which they are quite unfit. A little consideration of the individual and his bent will indicate whether he is to work chiefly with his brain or his hands. In the latter category, art, architecture, mechanical drawing, watch repairing, electrical and radio work offer opportunities. In some communities vocational training of the kind required by hemophiliacs is available.

Ten of the 28 hemophiliacs over 20 years of age in our series are married and have a total of 13 children. To advise against marriage simply adds another probably unnecessary burden to an already troubled life. However, one can ensure that both partners understand fully the nature of the disease and their responsibility both as to its hereditary implications and to the prognosis for future morbidity. The decision is then left to the individuals concerned. It is certainly well for the prospective bride to have a possible gainful vocation in case of prolonged illness of her husband, but many of our hemophiliacs have been able by careful planning to provide an adequate home.

The hemophiliac is continually exposed from an early age to those who feel sorry for him, want to help him, or even consider him an inferior. In addition, he has frequent illnesses and must bear considerable pain. It requires a strong mental constitution to become adjusted to such a life. Fortunately, most hemophiliacs accept their additional burdens as they come and in this way each period of stress builds a better adjusted individual. The physician by frequent discussions is in a position to aid greatly the individual's own effort to learn to live with his disease.

# STUDIES ON AN UNDETERMINED CIRCULATING ANTICOAGULANT CASE REPORT AND LABORATORY FINDINGS

By D G DIETER, M D , M SPOONER, M A , F J POHLE, M D †

## INTRODUCTION

IN 1940, Lozner, Joliffe and Taylor<sup>1</sup> reported the case of a 61 year old male Negro with an undetermined circulating anticoagulant. More recently, Lawrence and Johnson,<sup>2</sup> and Munro<sup>3</sup> have reported studies on male patients, previously diagnosed as hemophiliacs, who developed a circulating anticoagulant following numerous blood transfusions. Madison and Quick<sup>4</sup> presented a case and reviewed several other cases of female patients with hemorrhagic diatheses characterized by prolonged coagulation times.

The circulating anticoagulants present in the patients of Lozner et al,<sup>1</sup> Lawrence and Johnson,<sup>2</sup> and Munro,<sup>3</sup> although never identified, had the following common characteristics: (1) they prolonged the coagulation time of normal blood, (2) they were thermostable, (3) they showed no antithrombic activity, (4) they were not neutralized by protamine, (5) they did not pass through semipermeable membranes, (6) they were not extracted by ether. Lozner and his associates found that the anticoagulant material which they described was not associated with the euglobulin fraction which contained the antihemophilic property of plasma. Munro found that the anticoagulant with which he was working was not precipitated as euglobulin. Munro noted that the anticoagulant, when precipitated as a globulin, maintained an anticoagulant activity equal to that of the plasma from which it was derived. It was also stable in a pH of 6.5 to 11.0. So far as history and clinical observation is concerned, it is relatively certain that the patient described by Lozner and Taylor was not a case of hemophilia.

The patients reported by Madison and Quick<sup>4</sup> and referred to as hemophilia like were probably similar to those already described, although the data presented are insufficient to make a positive statement. The fact that the patients discussed by these authors, in spite of the fact that they may have had different diseases, had an increased coagulation time as the only abnormal finding suggests an anticoagulant with the same characteristics as those investigated by Lozner et al,<sup>1</sup> Lawrence and Johnson,<sup>2</sup> and Munro.<sup>3</sup>

This paper presents the history, hematologic studies, and clinical course of a patient with a prolonged coagulation time due to an undetermined anticoagulant. This anticoagulant appears to be similar to those which were present in the above mentioned cases.

## REPORT OF CASE

The patient, a 68 year old white male banker, was admitted to Madison General Hospital on October 12, 1946 complaining of loss of appetite for five days prior to admission. This was followed by generalized muscular aches, pains in the extreme lower abdomen, and gross hematuria.

From the Departments of Medicine and Physiology, University of Wisconsin Medical School, Madison, Wisconsin.

This study was aided by a grant from the Wisconsin Alumni Research Foundation.

† Deceased.

*History of present illness* The patient had apparently been in good health until eight months before admission at which time he developed what appeared to be a contact dermatitis on the back of his right hand which gradually spread over both arms and back. This was treated with sulfathiazol ointment with no improvement. Two weeks after the onset he was admitted to the State of Wisconsin General Hospital where he was treated with boric acid compresses and boric ointment. He recovered and was discharged on the sixth hospital day.

The patient was readmitted to the Wisconsin General Hospital one month later because of recurrence of the skin lesions. The condition was diagnosed at this time as pemphigus and the patient was treated with stovarsal 50 mg before breakfast for three days. After a three day interval in which no drug was given the dose of stovarsal was increased to 100 mg daily. With this regimen the process slowly subsided and the dose was gradually increased to 250 mg of stovarsal daily for three successive days followed by three day rest periods. The patient was discharged on the sixty-seventh hospital day and followed as an out patient for the next three months. While an out patient, he received the same therapy for two months with complete disappearance of all skin lesions except for a small bullous lesion on the left hand.

Approximately two months prior to admission to Madison General Hospital, the patient developed an acute painful swelling of the left elbow. This was thought to be an acute bursitis. The joint was aspirated and blood was obtained. A pressure bandage was applied and no further bleeding occurred. Later, 2 large ecchymotic areas developed on his right arm while he was bair casting. These gradually subsided.

*Past Medical History* The patient had a benign bladder tumor fulgurated twelve years prior to admission.

*Family History* No other members of the patient's family had had any hemorrhagic diatheses.

*Physical Examination* The patient was a well developed, fairly well nourished man who did not appear acutely ill. The temperature was 99.6 F, the pulse rate was 80, the blood pressure 150/80 mm Hg.

The vessels of the optic fundi showed a grade 2 sclerosis with no evidence of hemorrhage or exudates. A few palpable cervical and axillary nodes were present. There were a few scattered, fine crepitant rales in the posterior lung fields bilaterally. The left cardiac border was percussed 1 cm outside the mid clavicular line. There were grade 1 apical and aortic systolic murmurs which were not transmitted. The liver edge was palpable 2 cm below the right costal margin and was nontender. The spleen was not palpable. There was moderate tenderness over the left side of the abdomen at the level of the umbilicus. Bilateral indirect inguinal hernias were present. Vibratory sense was absent in the left leg. Sternal tenderness was noted.

The preliminary laboratory studies were as shown in table 1.

On cystoscopic examination, blood was seen coming from the left ureter.

X ray studies of the chest were negative for signs of tuberculosis and pneumonitis. A retrograde pyelogram of the left kidney revealed that the kidney was displaced upward. X ray studies of the kidneys, ureter, and bladder taken after the retrograde pyelogram showed small areas of opaque material in the region of the left kidney pelvis which was interpreted as the contrast material of the retrograde pyelogram incorporated in blood clots.

*Clinical course* The patient's stay in the hospital was characterized by exacerbations of bleeding followed by a quiescent period during which the patient improved. On one occasion his condition appeared terminal. Auricular fibrillation developed with evidence of decompensation. The blood nonprotein nitrogen became elevated and symptoms and signs of uremia followed. There was a gradual recovery from this acute phase. Numerous episodes of spontaneous hemorrhages occurred which involved the upper and lower extremities. At one time the hemorrhage into the left arm was so extensive that a left radial palsy resulted. There were intracapsular hemorrhages into the shoulder, elbow, hip and knee joints. On two occasions bleeding occurred into the tongue with extension into the sublingual region and the pharynx. There were two episodes of gross hematuria. On several occasions the physical findings were compatible with intra abdominal and retroperitoneal bleeding. There was one episode of severe low back pain associated with clonic contractions of the muscles of the back and both lower extremities. It was thought that this resulted from an extensive hematoma compressing the spinal cord. At one time there was hemorrhage into both parotid capsules. Progressively, however, it appeared that the patient was slowly improving, for the episodes of bleeding were not as frequent and the hemorrhages

were less extensive. Because of the futility of the treatment and the low morale of the patient he was discharged on August 16, 1947. His condition has improved subjectively since discharge. There has been increased appetite. The radial nerve palsy has disappeared. There have been no new episodes of bleeding up to the present time, even though a coagulation time done after two months at home was 90 minutes.

**Therapy.** Along with the supportive measures that were necessary to control pain, combat the persistent anemia and maintain the patient in the best possible state of nutrition and hydration, specific therapeutic agents were employed in an attempt to control the bleeding tendency. Blood transfusions, plasma, concentrated albumin, intravenous calcium gluconate, hemostatic serum, vitamins C, B, P and glucoside of quercetin (rutin) were administered until the condition could be further investigated. When it was discovered by adding the patient's plasma to normal whole blood that the coagulation defect was due to a circulating anticoagulant which prolonged coagulation time of normal blood, 50 cc. of 1 per cent solution of salmine protamine were given intravenously daily for fourteen days.<sup>7, 8</sup> This therapy failed to affect the coagulation time materially.

TABLE 1—*Resume of Laboratory Findings*

Erythrocyte count	1,570,000 to 4,130,000 cells per cu. mm. blood
Hemoglobin	5 to 12 Gm. per 100 cc. blood
Leukocyte count	8,200 to 19,500 cells per cu. mm. blood
Differential	neutrophils increased to 87% during febrile state
Sedimentation rate (Wintrobe)	4.5 mm. in one hour
Blood non protein nitrogen	29-75 mg. per 100 cc.
Hanger's test (cephalin-cholesterol flocculation)	2+ in 48 hours
Fasting blood sugar	87 to 129 mg. per 100 cc.
Icterus index	8 to 50 units
Total serum protein	4.5 to 6.4 Gm. per 100 cc.
albumin	1.5 to 3.1 Gm. per 100 cc.
globulin	1.8 to 4.4 Gm. per 100 cc.
Serology	negative

### METHODS

The experimental techniques used in these investigations were kept as uniform as possible. All blood samples were drawn in cooled, oiled syringes. When citrated plasma was used, the blood was obtained by venipuncture and mixed with 3.8 per cent sodium citrate in the ratio of 9:1. The mixture was kept in an ice bath until used. With the exception of the studies on the effect of high and low centrifuging and platelet activity, the blood was centrifuged at 1500 rpm for ten minutes at 4°C. When uncitrated plasma was used, clustroid tubes were substituted for glass.

The Lee-White method was used in determining the coagulation times of whole blood. In studying the anticoagulant, glass tubes 13 mm. in diameter were placed in a water bath at 37°C. and all clotting times were determined at that temperature. The reagents used in all experiments were also kept at 37°C. The volumes utilized in the individual studies were maintained at 1 ml. except in several specified instances. With a calcium chloride concentration of 0.025 M the coagulation time of recalcified normal plasma was 2-3 minutes, that of normal uncitrated plasma, 4.5 to 5.5 minutes.

*Effect of citrated normal human plasma on the coagulation time of the patient's blood* To determine whether human plasma in minute quantities would shorten the coagulation time of the patient's blood, the proportions were set up as shown in table 3. Small amounts of normal plasma shortened the coagulation time of the patient's blood to some extent, but did not return the coagulation time to normal limits. The coagulation time changed very little when larger amounts of normal plasma were added to the patient's blood.

*Effect of patient's citrated plasma on the coagulation time of normal blood* Amounts of patient's plasma varying from 0.1 ml. to 0.003 ml. were added to 2 ml. of normal blood. In all cases, isotonic salt solution was added in sufficient quantity to make the volume of the patient's blood preparation equal to 0.1 ml. The results are given

TABLE 2.—*Special Hematologic Studies*

Platelet count (direct wet method)	216 000 to 324 000 per cu. mm. blood
Bleeding time (Duke)	1.5 to 3.5 minutes
Coagulation time (capillary tube)	4.5 to 4.5 minutes
(Lee White)	90 to 270 minutes
Clot retraction	normal in 24 hours at 37 C.
Tourniquet test (Rimpel Leede)	normal
Prothrombin concentration (Quick)	91 to 105%
Fibrinogen	normal
Ascorbic acid (fasting whole blood)	0.40 mg. per 100 cc.
(fasting plasma)	0.13 mg. per 100 cc.
Anthr thrombin activity of serum (Wilson)	normal

TABLE 3.—*Effect of Citrated Normal Human Plasma on the Coagulation Time of the Patient's Blood*

	Coagulation Time
	minutes
2.0 ml. patient's blood (control)	127
2.0 ml. patient's blood + 0.01 ml. normal plasma	84
2.0 ml. patient's blood + 0.03 ml. normal plasma	83
2.0 ml. patient's blood + 0.05 ml. normal plasma	68
2.0 ml. patient's blood + 0.10 ml. normal plasma	129
2.0 ml. patient's blood + 0.20 ml. normal plasma	120

in table 4. These data show that an anticoagulant activity was present in the patient's plasma.

*Effect of the patient's uncitrated plasma on normal uncitrated plasma* It was found that when dilutions ranging from 0.05 to 0.20 ml. of the patient's uncitrated plasma were added to 0.4 ml. of normal uncitrated plasma, with 0.15 M sodium chloride added to make a volume of 1.0 ml., the effect, although not as marked as that shown in Tables 4 and 5, showed some tendency toward prolongation.

*Effect of patient's citrated plasma on normal citrated plasma* The above experiment was repeated with citrated normal and patient's plasma to which was added 0.4 ml. of 0.025 M calcium chloride and 0.15 M sodium chloride to make a total of 1.0 ml. The results of this and a control are shown in table 6.

The data show that when increased amounts of the patient's plasma, previously recalcified, are added to 0.4 ml of normal plasma, the coagulation time is increased. The effect is not extremely marked until 0.4 cc of the patient's plasma is added, in which case it is shown that equal amounts of normal plasma and patient's

plasma give a coagulation time of over 23 minutes. A control experiment, adding recalcified normal plasma to normal plasma did not show this type of change.

Effect of high and low centrifuging on patient's citrated and uncitrated plasma as compared with the normal. To rule out hemophilia further, samples of citrated and un-

citrated patient's and normal blood were submitted to high (3000 rpm for five minutes) and low (1000 rpm for five minutes) centrifuging. Quick<sup>4, 5</sup> has observed that after high centrifuging the coagulation time of recalcified hemophilic plasma is considerably slower than that obtained by spontaneous sedimentation or low centrifugation. This could not be demonstrated on the plasma of this patient. The findings are recorded in table 7.

Samples of citrated and uncitrated blood from the patient and from a normal individual were submitted to centrifugation at 3000 rpm per minute for five minutes and also at 1000 rpm for five minutes. This experiment was done in order to determine whether or not the same relation to spinning blood at 3000 rpm and 1000 rpm, which Quick found in hemophilia, applied to the blood of this patient. No such similarity was obtained.

*Effect of salmine protamine and toluidine blue on the coagulation times of patient's and normal blood*<sup>6-8</sup>. Although it has been stated above that salmine protamine was

TABLE 7—Effect of High and Low Centrifuging on Patient's Citrated and Uncitrated Plasma as Compared with the Normal

	Normal Plasma	Patient's Plasma	0.15 M NaCl	0.025 M CaCl <sub>2</sub>	Coagulation Time
	ml	ml	ml	ml	min

It was found that by employing the technique outlined in the explanation of methods, normal blood remained unclotted for over 90 minutes and the patient's blood was not coagulated 6 hours later.

used intravenously with no appreciable reduction of the clotting time, experiments were performed to test the effectiveness of it, and toluidine blue in vitro. Amounts of a 0.1 per cent solution of the two drugs, ranging from 0.02 to 0.10 ml, were added to 0.20 ml of the patient's citrated plasma which was diluted to 1.0 ml with 0.15 M sodium chloride and recalcified with 0.40 ml of 0.025 M calcium chloride. It was found that these drugs further prolonged the coagulation time of recalcified patient's plasma. This experiment was repeated using normal blood with similar results.

To test the effectiveness of these drugs to neutralize the anticoagulant properties of heparin, 1 unit of heparin was added to 0.20 ml of normal plasma. The reagents salmine protamine, toluidine blue, 0.15 M sodium chloride and 0.025 M calcium chloride were added in the same order and amounts as discussed in the previous paragraph. These studies showed that 1 unit of heparin prolonged the coagulation time of normal recalcified plasma to 11 minutes (normal 2-3 minutes) and that

0.02 ml of either of the two drugs being tested reduced the clotting time to 4.5 minutes. Amounts in excess of 0.02 ml of salmine protamine and toluidine blue prolonged the coagulation times.

### *Studies on Platelet Fragility*

Studies on platelet fragility were performed according to the method of Muhre, Bogart and Hogan<sup>9</sup> by combining the patient's recalcified plasma with concentrations of sodium chloride varying from 0.33 to 2.5 per cent. The results of these experiments show that the clotting time obtained with 0.8 per cent saline solution was found to be the same as that obtained with recalcified plasma, i.e., 10 minutes.

TABLE 8—*Studies on Platelet Activity*  
Recalcification was carried out in each instance with 0.40 ml of 0.025 M  $\text{CaCl}_2$

Platelet Poor Plasma	Saline Suspension of Platelets	0.15 M NaCl	Coagulation Time
ml	ml	ml	min
0.20 normal	0.20 normal	0.20	2.0
0.20 normal	0.20 patient	0.20	3.0
0.20 normal	0.00 —	0.40	5.5
0.20 patient	0.00 —	0.40	16.0
0.20 patient	0.20 patient	0.20	12.0
0.20 patient	0.20 normal	0.20	10.0

TABLE 9  
Test System: 0.20 ml patient's citrated plasma + 0.40 ml normal plasma + 0.40 ml 0.15 M NaCl + 0.40 ml 0.025 M  $\text{CaCl}_2$

Conditions to which Patient's Plasma was Subjected	Coagulation Time
	minutes
4 degrees C. for 24 hours	3.0
Room temperature for 4 hours	3.0
61 degrees C. for 10 minutes	7.5
Unheated plasma	6.5

When the sodium chloride solution became hypertonic the coagulation time was prolonged. This procedure was repeated on normal plasma with similar findings.

### *Studies on Platelet Activity*

To rule out further the possibility that the platelets were responsible for the coagulation defect, a study of platelet activity was carried out according to the method described by Patek and Stetson.<sup>11</sup> The technique for drawing and citrating the blood was that of previous experiments except that paraffin-coated tubes were used instead of glass. The pipets used in these studies were coated in the inside with a thin film of collodion. Plasma was obtained by centrifuging the blood at 1500 rpm for ten minutes. This plasma was withdrawn and centrifuged at 4200 rpm for fifteen minutes to produce platelet-poor plasma. The platelets were separated

from the platelet-poor plasma and were washed in normal saline and resuspended in a volume of 0.15 M sodium chloride equal to the original volume of plasma. The results of this experiment are shown in table 8.

The data indicate that there was no essential difference in the activity of platelet suspension obtained by this technic and that obtained from normal blood and from the blood of the patient.

*Effect of cold storage, room temperature, and heat on coagulation time of patient's citrated plasma* Citrated samples of the patient's plasma were subjected to 4 degrees Centigrade for twenty-four hours, room temperature for three to four hours, and 61 degrees Centigrade for ten minutes. It was found that heat did not destroy the anticoagulant, but when the plasma was allowed to stand at room temperature for four hours or in a refrigerator at 4 degrees Centigrade for twenty-four hours, the coagulation time of patient's plasma was normal (2-3 minutes) and the anticoagulant action on normal plasma had disappeared as shown in table 9.

#### *Effect of Dialysis*

Ten ml. of the patient's plasma, prepared in the usual manner, were placed in a viscose casing bag and allowed to rotate in distilled water for a period of twenty-four hours at 4 degrees centigrade. The dialysate and the contents of the bag were found to have no anticoagulant activity.

#### *Electrophoretic Analysis*

The  $\alpha/\gamma$  ratio was found to be 0.63. The patient's plasma was submitted to electrophoretic analysis. Increased amounts of each of the globulin fractions were reported. However, as a whole, the pattern of the globulin proteins was not remarkable. The actual analyses for albumin and globulin, based on the Sherring diagram was 2.9 Gm. per cent albumin, 4.6 Gm. per cent globulin per 100 ml. of plasma.

### DISCUSSION

The known hemorrhagic diatheses, such as increased capillary fragility, thrombocytopenic purpura hemorrhagica, afibrinogenemia, hemophilia, pseudohemophilia, hypoprothrombinemia, athromboplastinopenia and afibrinogenopenia have been ruled out either by the history or laboratory findings, as summarized in table 1, or by the therapy that the patient received.

The discovery that the patient's plasma prolonged the coagulation time of normal blood established the presence of a circulating anticoagulant. The investigative results of the patient's coagulation defect do not place this anticoagulant in four of the five categories postulated by Quick,<sup>8</sup> namely, decalcifying agents, antiprothrombins, antithrombins and fibrinogen antagonists. The question of whether antithromboplastin is present is not clearly answered.

The presence of any one of these factors as the cause for the defect in the coagulation mechanism, although not positively ruled out, has at least been eliminated except for antithromboplastin. The studies show that the patient's anticoagulant was not destroyed at 61 C. for ten minutes, while the antithromboplastin described

by Tocantins was destroyed by heat Munro's<sup>3</sup> argument that there possibly exists more than one antithromboplastin is logical

The investigative work conducted on this patient was as complete as possible with the available techniques The data accumulated are similar to those obtained by Lozner et al.,<sup>1</sup> Lawrence and Johnson,<sup>2</sup> and Munro<sup>3</sup> regarding the nature of the anticoagulant with one probable exception, namely, their anticoagulant was stable to storage as well as heat, a finding which is probably not altogether true for this patient, so far as one may judge by a comparison of table 3 and 8 However, if one can compare the data of whole blood and plasma as is necessary in these experiments, one would judge that at least part of the antithromboplastic or anticoagulant activity was destroyed Neither the anticoagulant described by these workers nor the one described here passed through semipermeable membranes It is thought, however, that the results obtained on these studies are comparable to those reported by other investigators on patients with similar afflictions and hence this case probably belongs in the same or a similar category

The factor which precipitated this hemorrhagic diathesis is as obscure as in the case reported by Lozner et al.<sup>1</sup> It is possible that the pemphigus was the exciting factor Stovarsol cannot be eliminated, even though routine laboratory studies during the period that the drug was used were in no way unusual Coagulation times (capillary tube method) of 5 patients with pemphigus, who received stovarsol therapy, were within normal limits Another possibility is that the prolonged coagulation time would have occurred spontaneously Unlike the patients of Lawrence and Johnson<sup>2</sup> and Munro,<sup>3</sup> our patient had a coagulation defect prior to the administration of multiple transfusions

### CONCLUSIONS

The results of various studies upon a patient with a coagulation defect are reported The cause of this defect was found to be a circulating anticoagulant, whose exact nature remains obscure

### ACKNOWLEDGMENT

The authors are indebted to Dr. Ovid O. Meyer for criticisms and suggestions in preparation of the manuscript to Dr. John Malec of Madison General Hospital for permission to use the clinical material to Eli Lilly & Company for the protamine to Dr. P. P. Cohen and Miss Frances Thompson of the Department of Physiological Chemistry for the electrophoretic and fibrinogen analyses

# FAMILIAL PANMYELOPHTHISIS

## FANCONI SYNDROME IN ADULTS

By KARL ROHR, M D

THE FOLLOWING case histories are of interest because they are the first reports of a familial panmyelopathy of the hypoplastic type occurring in adults. Two brothers were affected.

### CASE REPORTS

*Case 1.* Sch., Franz, was born in 1921. As a boy he was nicknamed "the negro" because of marked pigmentation. He was healthy apart from bouts of eczema.

In 1939, at the age of 18, he had poliomyelitis with resulting weakness of the abdominal muscles. Anemia was discovered for the first time during this illness, with hemoglobin levels varying between 60 and 80 per cent. In April 1945 the hemoglobin was again 60 per cent. In August 1945 the hemoglobin had declined to 53 per cent and in September to 51 per cent. He was given transfusions and Ferredoxin therapy and his hemoglobin rose to 80 per cent. When seen early in 1946 after accidental burning of one arm, his hemoglobin had again dropped to 48 per cent and he was transfused. In June of that year his hemoglobin was 65 per cent. He complained of being very tired and developed dyspnea with little exertion. He also complained of severe pains in the tibiae and vertebrae, slight edema and gingivitis. In November 1946 three teeth were extracted because of stomatitis and this was followed by fever ranging between 38 and 40 C. there was profuse bleeding, the hemoglobin declining to 30 per cent and later to 24 per cent. Temporary improvement followed transfusions and penicillin therapy. Later that year he had bronchopneumonia and his hemoglobin was found to be only 10 per cent. He died in March 1947 at the age of 26 years.

Physical examination showed that the form and the size of the head were normal, as were the genitalia. The skin showed a marked greyish pigmentation, especially on the face, forearms and to a lesser extent on the abdomen. Petechiae were seen in the skin and mucous membranes in 1944 and in November 1946 at the time of the teeth extraction he showed marked pallor, gingivitis, stomatitis and glossitis and there were hemorrhages in the fundi of the eyes. The heart was found to be slightly enlarged and in September 1945 the blood pressure was 130/70. The electrocardiogram was normal at that time but in November 1946 showed signs of myocardial damage.

The urine showed urobilinogen and indican but no porphyrin. Serum bilirubin was 0.3 mg per cent and phosphates and phosphatase were normal. The Takata Ara reaction was negative, the Weleman coagulation time was 0.25 (enlarged) and the serum proteins were 6.8 Gm per cent.

*Hematologic findings.* The course of the anemia has already been indicated and is shown in figure 1. The red cell counts initially were between 2.7 and 3.5 million per cu mm, later dropping to 1.1 to 1.2 million per cu mm and finally to 660,000 per cu mm. The color index varied from 0.96 to 1.39 but was usually over 1.2.

The white blood cells in 1939 were 2,700 to 8,300 per cu mm. During 1945 the count was about 4,000 per cu mm at first, later dropping to between 2,000 and 4,000 per cu mm. In November 1946 the count was only 500 per cu mm and finally reached as low as 310 per cu mm. The polymorphs were 63 per cent at the beginning, with 25 per cent lymphocytes. This gradually changed so that the polymorphs dropped to 58 per cent and then to 34 per cent, the lymphocytes rising to 31 per cent and later to 60 per cent. Monocytes varied between 4 and 10 per cent and the eosinophils between 1 and 3 per cent. The blood smear showed anisocytosis of marked degree throughout the illness, with macrocytosis and microcytosis and poikilocytosis. Polychromasia was marked for a long time. Reticulocytes were 2.4 per cent in June 1946 but later declined to 0.3 and 0.4 per cent.

The platelets were noted to be diminished in August 1945 and counts during the next year lay between 4,600 and 32,000, with a drop finally to 1,000 per cu mm.

From the Medical Department, University of Zurich, Switzerland.

The bleeding time was 5 minutes, and 1 1/2 minutes and the coagulation time was normal on two occasions (5 minutes). The osmotic fragility test showed initial hemolysis in 0.44 per cent NaCl and complete hemolysis in 0.32 per cent NaCl.

The sedimentation rate was first found to be high in 1944. Readings by the Westergren method showed results of 60 to 101 in the first hour and 76 to 130 in the second hour except for readings of 30 for the first hour and 60 in the second hour after transfusions had raised the hemoglobin to 30 per cent. In the terminal stages of the illness the readings were 172 and 175 in one and two hours respectively.

Bone marrow studies during life are of interest. In 1945 smears showed abundant marrow macroblastosis and increase of the metamyelocytes and stab forms. In 1946 the marrow showed a good deal of fat hypocellularity with few basophilic erythroblasts and myelocytes and almost no neutrophils, but a great increase in the reticular cells of the lymphoid and plasma cell types (fig. 2). In 1947 the marrow was even poorer in the normal cell types. Lymphoid and plasma cells predominated, being seen in groups of 6 or 8. Lymphocytes were also increased, in parts a great many fibrocytes with fibril formation were seen, and there were also an unusual number of tissue mast cells as many as 4 or 5 per field (fig. 3).

FIG. 1. COURSE OF THE BLOOD COUNTS IN SCH. FRANZ

**Autopsy report.** The heart showed dilatation with hypertrophy of the left side and hemorrhages into the endo- and myocardium. There was bronchopneumonia at the right lower lobe. The liver showed fatty degeneration. The brain showed slight bleeding. There were extensive hemorrhages into the mucous membranes. Generalized hemosiderosis was observed throughout the whole reticulo-endothelial system and in the liver cells. Brown iron free pigmentation of the skin was also observed. Rudimentary centers of blood formation with development of megakaryocytes were found in the lymph nodes and spleen. Areas of chronic inflammation were seen in the suprarenal medullae and in the interstitial tissue of the kidneys.

**Case 2 Sch. Willi.** The younger brother was born in 1923 and is now 25 years old. The course of his illness is shown in figure 4.

Past illnesses were whooping cough, measles, mumps and bronchitis during childhood and appendectomy at the age of 15.

The present illness started in November 1943 at the age of 20 with a cold which was followed by pneumonia of the left lower lobe while the patient was in military service. Following Cabazol therapy the pyrexia diminished but a low grade fever continued and a high sedimentation rate persisted with readings of 90 mm in the first hour and 105 mm in the second hour (Westergren). The hemoglobin at the onset of the illness was 86 per cent later dropping to 60 per cent.

Following blood transfusion therapy the hemoglobin was 86 per cent but later dropped and the anemia became even more severe. The disease continued to progress, with a hemorrhagic tendency always the most prominent feature, with especially bad bleeding following the extraction of a tooth. He continued to run a low grade fever with temporary bouts of higher pyrexia of unexplained origin. Occasional episodes of diarrhea which were resistant to therapy occurred. In 1945, the patient began to suffer from

FIG. 2. STERNAL PUNCTURE OF SCH FRANZ

(a and b) Microphotographic enlargement ( $\times 1000$ ) Clusters of plasma cells with central reticular cells

(c) From the same slide photograph from watercolor picture. Smaller basophilic stroma cells (plasmacytic, histiocytic and fibrocytes-like cells)

violent pain in the bones, and had intercurrent eosinophilic infiltration of the lungs and an attack of epidemic hepatitis. At times there was spontaneous improvement in his condition. The disease was resistant to all forms of therapy including sulfonamides, penicillin in large doses, iron and massive doses of vitamins. Temporary improvement could be brought about only by transfusions. He was given more than 70 transfusions totalling about 20 liters of blood.

Because of the failure of all other therapeutic measures splenectomy was carried out in September 1945. Following operation the hemoglobin increased to 70 per cent, the bleeding tendency ceased the

general condition improved and the weight increased. However, a few weeks after operation the anemia again increased with a recurrence of bleeding into the skin. Violent pains occurred in the bones of the legs and thighs, in the shoulder blades and the vertebral column. The skin of the legs gradually became

FIG. 3 STERNAL PUNCTURE OF SCH. FRANZ

(a and b) Microphotographic enlargement ( $\times 1000$ ) Various tissue mast-cells besides connective tissue and small lymphoid reticular cells

(c) Two isolated mast cells in aplastic anemia, photograph from a watercolor picture. Note the coarse eosinophilic granulation and the protoplasmic pseudopodia

greyish like smoke with dark pigmented spots. At the beginning of January 1946 the patient was given high altitude therapy in the Engadine. His clinical condition became stationary with frequent violent pains in the legs and pigmentation of the hands. The hemoglobin at this time was 65 per cent.

The clinical condition remained unchanged up to the end of April 1947. The patient had been able to do some light work for several months. He often complained of violent boring pain in the bones of legs

the cervical vertebrae, the shoulder blades and the bones of the jaw. After preparation by blood transfusions, 11 decayed teeth were extracted without any severe bleeding. Only rare bleeding into the skin and epistaxis had occurred and there had been no hematuria. The temperature had been only slightly elevated except during an influenzal infection. The hemoglobin on March 30, 1947, was 59 per cent. Liver and folic acid therapy were without effect.

Physical examinations done at various times during the illness showed striking pigmentation of the skin, especially around old scars, as well as brownish spots of pigmentation on the mucous membrane of the mouth. The skin was delicate and decidedly, smoke grey in color, particularly on the legs and thighs, and to some extent on the arms and body. In a few places some darker spots were noticed. It was observed that the patient had a slender skull and x rays revealed a thin skull with a small sella turcica. The structure of the body was somewhat asthenic and gave the impression of being slightly infantile. There were few hairs on the body, with hardly any beard growth and feminine genital hair distribution (fig. 3). He was found to be intellectually normal. No abnormalities were found by x ray in the pelvic bone, femur or humerus.

FIG. 4. COURSE OF THE BLOOD COUNTS IN SCH. WILLI

The urine gave a slightly positive test for urobilin and occasionally showed a few isolated red cells. Free hydrochloric acid was present in the stomach. The stools contained increased amounts of fats, but no increase of urobilin. X rays showed the stomach and intestines to be normal. The electrocardiogram showed deflection of the T wave in the second lead but was otherwise normal. The basal metabolic rate was +4 per cent.

Blood chemistry showed total proteins varying from 7.0 to 7.8 gm per 100 cc, cholesterol 147 to 173 mg per 100 cc, serum iron 171-215 gamma per 100 cc, calcium 9.5 mg per 100 cc, nonprotein nitrogen 27 mg per 100 cc, the uric acid 4.2 mg per cent and the bilirubin 0.3 mg per cent except during the attack of epidemic hepatitis when it rose to 6.2 mg per cent. The Takata Ara reaction was negative and the Weltman coagulation band was 0.2 (enlarged).

The Wassermann, Pitquet and Mantoux reactions were negative, and repeated blood cultures were also negative.

**Hematologic findings.** The hemoglobin varied between 59 and 65 per cent except after transfusions and a rise to 70 per cent following splenectomy. The red cell count varied from 2.4 to 3.0 million per cu mm.

FIG. 5 SCH. WILLI

Note the slight infantile aspect, the feminine hair growth and the pigmentation of the skin, especially on the legs. Status after splenectomy.

and the color index from 1.0 to 1.3. The white cell count showed leukopenia, 2,800 to 4,500 except after transfusions and after splenectomy when it rose to 5,500. Neutrophils were 39.5 to 45.5 per cent.

FIG. 6. BLOOD PICTURE OF SCH. WILLI

Microphotographic enlargement ( $\times 1000$ ) Note the enormously developed anisocytosis in (a) macrocytic and microcytic (schistocytes) forms and in (b and c) the target cells

sinophils 0.5 to 5.0 per cent, basophils 0.0 to 0.5 per cent, monocytes 9 to 12 per cent, lymphocytes 40 to 57 per cent with a rise to 63 per cent following splenectomy and 1.5 per cent plasma cells were seen on one occasion. The platelets were markedly reduced 25 000 to 46 000 except immediately after splenectomy when they were 66 000. The reticulocytes were 1.1 to 2.3 per cent. Blood smears (fig. 6) showed

anisocytosis with very large and very small cells poikilocytosis, polychromasia, and even before splenectomy erythroblasts and Howell Jolly bodies were present

The bleeding time was 6 minutes with a temporary rise to 30 minutes in 1945. The prothrombin time was 40 per cent later 100 per cent. The coagulation time was 1 to 12 minutes. The osmotic fragility test showed initial hemolysis in 0.5 per cent NaCl and complete hemolysis in 0.1 per cent NaCl.

The sedimentation rate was persistently elevated. Early in the disease it was 45 mm in the first hour and 75 mm in the second hour by the Westergren method rising to 70 mm and 110 mm in the first and second hours respectively except for readings of 8 and 15 respectively during a remission in the anemia. In April 1946 the readings varied from 18/39 to 26/45 and in March 1947 the result was 28/47.

FIG. 7. PRICE JONES CURVE OF THE FOUR BROTHERS

Note in comparison with the normal curve the deflation and broadening of the curve especially toward the right, a tendency which is strongly marked in the still living patient, Sch Willi; in the deceased Sch Franz less remarkable and scarcely noticeable in the healthy brothers.

**Histologic findings.** The spleen histologically showed moderate thickening of the capsule and trabeculae as well as thickening and hyalinization of the intima of the follicular arteries. The pulp contained copious amounts of red cells with a moderate number of lymphocytes, some neutrophils and eosinophils, numerous hemosiderin-containing pulp cells and some plasma cells. The venous sinuses were also enlarged. A diagnosis of chronic splenomegaly and hemosiderosis was made.

Sections of a growth excised from the subcutis of the leg showed perivascular lymphatic infiltrations with some isolated polymorphs. Numerous hemosiderin-containing cells were found in the connective tissue as well as in the corium.

Sections of the bone marrow also showed numerous hemosiderin-containing macrophages and a few lymph follicles. The bone marrow was also studied by sternal puncture done seven times during the course of the disease. The corticalis was moderately hard. At first the marrow was rather abundant but later became scarce. The most consistent finding was an increase of the immature myelocytes and of big ba

toxic erythroblasts while megakaryocytes were seen rarely. In several punctures many reticular cells, especially larger and smaller plasmacytic forms were present. On one occasion tissue mast cells were remarkably abundant and they were seen in a few other instances especially in places where the bone marrow was thick.

*Family History* The maternal grandparents died at 70 and 84 years of age both of cancer of the stomach. The father is 56 years old. The mother is 53 years old and suffers from mild hypertension but is otherwise well. Of 8 paternal uncles and aunts one has tuberculosis and 2 suffer from chronic polyarthritis. Two brothers are living and well. There were twin sisters, one of whom was stillborn and the other died one hour after birth.

Of 45 relatives examined only 2 showed hematologic abnormalities. In 2 otherwise healthy brothers, with hemoglobins of 100 and 102 per cent and red cell counts of 4.8 and 5.0 million per cu. mm. respectively the Price Jones curves showed a tendency to widening of the base both to the macro- and microcytic sides (fig. 7). Their reticulocytes sometimes rose to 2.0 and 2.4 per cent and the serum iron concentrations were 140 and 165 gamma per 100 cc. Osmotic fragility tests showed initial hemolysis in 0.45 and 0.46 per cent NaCl respectively and complete hemolysis in 0.30 per cent NaCl in both.

The second patient and the parents were Rh positive.

## DISCUSSION

One of the notable features of the disease in these two brothers lies in their strikingly analogous clinical symptomatology. The features common to both cases may be listed as follows:

1 *Age of onset of symptoms* In the case of the elder brother, symptoms began when he was 24 years old, although signs were already present five years earlier. The younger brother became ill at the age of 20.

2 *Pigmentation* In both patients an abnormal pigmentation of the skin attracted attention, showing sometimes a brown, sometimes a more smoky grey color. Pigmentation was present in one brother even before other manifestations of the disease appeared, and in the other patient the degree of pigmentation was greater than could be accounted for by the hemorrhagic diathesis or by the numerous blood transfusions.

3 *Hemosiderosis* In both cases, histologic examination revealed an abnormally marked hemosiderosis in the reticulo-endothelial system.

4 *Pain in the bones* Both patients complained at times of violent pain in the bones.

5 *Panhemocytopenia* In both cases the entire bone marrow was affected from the very beginning, with resultant anemia, leukopenia and thrombocytopenia.

6 *Hematologic findings* Both patients had a hyperchromic type of anemia, with a color index between 1.1 and 1.4. The erythrocytes revealed unusually marked anisocytosis with large macrocytes and some abnormally small microcytes (so-called schistocytes). Furthermore, in both cases there was a tendency to poikilocytosis, occasional target cell formation and to an abnormal amount of polychromasia. The number of reticulocytes was almost constantly above normal in both patients. The serum bilirubin was normal, the Takata-Ara test negative and the Weltman coagulation band enlarged and the Wassermann test negative.

7 *The morphology of the bone marrow* At the beginning of the illness only the signs of maturation arrest were apparent. Later, hypoplasia of the marrow parenchyma appeared which progressed to almost complete aplasia of the marrow in the patient who died. Moreover, in both cases, striking changes were present in the

stroma There was marked increase of small as well as larger forms of plasmocytic reticular cells (plasmocytosis), constant increase of the fibrocytes (fibrosis), and in addition unusually exuberant growth of the so-called tissue mast cells (mastocytosis), with as many as 4 to 5 such cells per field in some areas

Additional features of the disease are as follows (a) The younger, still living patient showed certain signs not observed in his brother, namely slight infantilism with deficient hair growth, microcephaly, a small hypophysis and hypogenitalism (b) In one patient the osmotic fragility of the red cells was increased at the beginning of the illness, while it was normal at the beginning of the illness of the other (c) In one patient a few Howell-Jolly bodies and erythroblasts were seen in the peripheral blood even before splenectomy (d) The level of serum iron was continually high in one patient, but was not determined in the other (e) There have been no previous reports in the literature of the occurrence in adults of a similar familial form of panhemocytopenia accompanied by such striking pigmentation Many cases of familial anemia, agranulocytosis and panmyelophthisis have been reported, especially by Gaennslen and Huber<sup>1</sup> However, the clinical picture of the two patients reported here seems to bear more resemblance to the constitutional panmyelopathy of children, described first by Fanconi<sup>2</sup> in 1927 and known as anemia perniciosiformis constitutionalis, or the Fanconi syndrome This disease has also been described by Uehlinger,<sup>3</sup> Zellweger and Zollinger<sup>4</sup> and by Dameshek and associates<sup>5</sup> The condition is characterized by a refractory macrocytic anemia with leukopenia and thrombopenia, brown pigmentation of the skin, microcephaly, atrophy of the testes and a tendency to deformities of the skeleton

Hematologically, we are apparently dealing with the same anomaly in the patients reported here Furthermore, as reported in the disease in children, these patients showed pigmentation of the skin, due apparently chiefly to hemosiderosis The infantile features were less pronounced here, though they could be seen distinctly in one of the patients The less pronounced degree of these changes seems to be connected with the relatively late development of the disease, which set in after the completion of puberty in both patients

Unlike the known aplastic anemias which are either normochromic or show a tendency to macrocytosis, it is of considerable interest to find in these patients an unusually marked anisocytosis with, on the one hand, very large macrocytes, and on the other hand, very small microcytes (so-called schistocytes), as well as poikilocytosis and target cell formation The reticulocytes were increased up to 20 to 30 per cent, whereas they are usually lacking in typical cases of aplastic anemia Although there was little or no increase of bilirubin in the serum, and the urobilin elimination in the urine was insignificant, there were various other factors which indicated pathological hemoglobin metabolism One indication was increased hemolysis, suggested by the high concentration of serum iron, the abnormal osmotic fragility of the erythrocytes and the number of reticulocytes Another was the pathologic iron storage throughout the reticulo-endothelial system, as indicated by the hemosiderosis of the various organs \* The increase of

\* This may have been due at least in part to the effects of multiple transfusions It is curious that exogenous hemochromatosis seems to develop much more extensively in cases of hypoplastic anemia than in some other cases of anemia given numerous transfusions *Editor*

hemolysis might be explained by assuming that a more exact balance of hemoglobin metabolism existed

The pathologic functioning of the reticulo-endothelial system in the two patients studied manifested itself not only in the generalized hemosiderosis, but also in changes in the bone marrow. As mentioned above, the changes in the reticulum and in the stroma of the marrow were especially remarkable, consisting of marked growth of the reticular cells, especially of the large and small plasmocytes, of the tissue mast cells and of the fibrocytes. These pathologic changes can be summed up with the designation reticulo-fibrosis of the bone marrow. The changes in the stroma seem to represent the primary disturbance, the first changes being plasmocytosis and mastocytosis. This results in maturation arrest of the normal marrow parenchyma which follows as the next stage of the process. With the evolution of the disease there ensues a kind of cicatrization process, an increase of the fibrosis with a gradual destruction of myeloid tissue and marrow atrophy is a still later stage of the process.

At present no definite answer can be given to the question of the physiopathologic importance of the enormous increase of the plasmocytes and mastocytes. However, it is known that both cellular forms should be classified in the reticulo-histiocytic system and that they belong to the so-called active mesenchyma. The plasma cells undoubtedly play an important part in the formation of globulin, particularly of gamma globulin, and hence in the development of antibodies. Thus, a relationship between plasma cells and certain immunity reactions appears to be important. On the other hand, the mastocytes, which show a genetic relation to heparin and amyloid, presumably have some connection with anaphylactic processes. \* It is theoretically possible that these particular plasmocytic and mastocytic changes of the bone marrow are an expression of an *anaphylactic-allergic process* of the bone marrow. In the light of these facts, it is noteworthy that in both patients the whole clinical picture developed in connection with an infectious disease (poliomyelitis and pneumonia respectively). Such a pathologic reaction of the reticulo-histiocytic system not only explains the primary reaction of the stroma of the bone marrow with a tendency to fibrosis of the marrow, but also accounts for the abnormal blood picture.\*

Other pathologic conditions of the reticulum or mesenchyma are known to be accompanied by even greater disturbances of the blood picture. This is true especially of osteosclerosis and osteomyelosclerosis, where the principal disturbances originate in the osteogenic reticulum, and in Cooley's anemia, where it is the disturbance of the myelogenic reticulum which seems to be chiefly responsible for the disturbances in the formation of blood. In these blood diseases, similar morphologic changes of the erythrocytes are found, namely marked aniso-, micro-, macro-, poikilocytosis, and target cells. These changes are much more pronounced in Cooley's anemia. In both these diseases there is not only a disturbance in the formation of blood but also a disturbance in the development of the bones. One

\* We have found tissue mast cells in the bone marrow in but a dozen cases and only in hypoplastic and aplastic anemias of various etiology (benzol poisoning, leukemia myeloma, infections and idiopathic forms).\*

disturbance is not the consequence of the other, but pathologic changes occur in both organs from the beginning. In Cooley's anemia, however, the pathologic blood formation is more striking, and in osteosclerosis the pathologic bone formation dominates the clinical picture.

It is not difficult to explain generalized hemosiderosis and pigmentation of the skin and mucous membranes as a consequence of pathologic functioning of the reticulo-histiocytic system. Abnormal hemolysins or agglutinins were not detectable in the two patients reported here. The parents and the patient who is still living are all Rh+.

#### SUMMARY

An account is given of a similar and hitherto unknown clinical-hematologic syndrome in two adult brothers with marked hemorrhagic diathesis, diffuse pigmentation of the skin, violent pain in the bones and panhemocytopenia. In the younger brother, there is also a certain degree of infantilism. The elder brother, died with all the symptoms of an intensive aplastic anemia, in the younger brother, the condition was stabilized after splenectomy. The blood picture in both patients was characterized by a hyperchromic anemia with remarkable micro- and macrocytosis, and an increased number of reticulocytes. In the younger brother, increased fragility of the red blood cells and an elevated serum iron content were observed. In both cases, an unusual increase of the plasmocytic and reticular cells and of the tissue mast cells was noticed in the bone marrow and, in the final stages of the disease, the marrow showed marked fibrosis.

The disease is believed to be a variety, in adults, of the syndrome first described by Fanconi as a constitutional panmyelopathy occurring in children. The illness is the result of a hereditary pathologic reaction of the reticulo-histiocytic system and seems to have been caused by an anaphylactic-allergic phenomenon. The possibility is discussed that genetic connections may exist between this condition and other diseases, such as certain osteoscleroses and Cooley's anemia, which are characterized by simultaneous disturbances of the bone and bone marrow and by a similar blood morphology.

## EXTRAMEDULLARY BLOOD PRODUCTION

By CLAUD MUNK PLUM, PH D

IN MAMMALS, throughout postnatal life, erythrocytes and granulocytes are normally produced only in the bone marrow, while the third type of circulating blood cell, the lymphocyte, is produced chiefly in the lymph nodes and the spleen, and only to a relative small extent in the bone marrow. During fetal life, blood formation occurs to a large extent in organs other than the bone marrow. It is well known that the liver and spleen take part in fetal blood formation and that this function ceases at birth, but no one seems to have investigated the function of the mammary and prostate glands with regard to existence and duration of hematopoietic activity within them. The observations to be reported at this time attempt to correlate the occurrence of extramedullary hematopoiesis in the mammary glands and the prostate, with the hematopoietic functions of the liver and the spleen.

Extramedullary blood formation by the newborn has been studied extensively in the past few years.<sup>1 7 10 11 12</sup> Bertelsen<sup>1</sup> investigated the origin of the erythrocytes during the last fetal months and the first days of extrauterine life, studying especially the liver, spleen and the thymus gland. Schlachta<sup>17</sup> found extramedullary foci in the prostate and the suprarenal glands, Block<sup>2</sup> in the kidneys and the renal pelvis, Gruber<sup>8</sup> in the mammary glands, and Weil<sup>10</sup> in the skin of the soles of the feet. The observations by Marchand and Lohlein<sup>14</sup> of extramedullary foci in the greater omentum and the sole of the foot laid the foundation for all the more recent investigations of the problems of extramedullary blood formation. These authors found that the perivascular cells, perhaps similar to Saxer's primitive histiocyte,<sup>16</sup> were the origin of the great stabformed types of basophilic and eosinophilic granulated cells and of the erythroblasts. The occurrence of the erythroblast in the greater omentum, however, was denied by Seifert.<sup>18</sup>

Weil's description of extramedullary hematopoiesis in the sole of the foot in human beings was based upon detailed investigations in only 4 cases.<sup>20</sup> The cells of the hematopoietic foci were found about the sweat tubules or in the adipose tissue. From his investigations the author concluded that the foci of blood formation always occurred in relation to the sudorific glands or to glands which might be a modification of sudorific glands, e.g., mammary glands. Weil's studies were continued by Dieterich,<sup>5</sup> who especially observed the mammary glands and the skin of the hand, foot, head and axilla. Dieterich's observations were based on a relatively large number of cases: 4 fetuses aged 2 to 6 months, 14 newborn individuals, 10 children aged 8 days to 3 years, and 11 adults. He found, in 10 newborn infants, that the pedal extramedullary foci were limited to the sole of the foot, no foci being present in the dorsum of the foot. This observation agreed with Weil's inference concerning the occurrence of hematopoietic tissue in relation to sudorific glands.

From the Department of Pathological Anatomy University of Copenhagen, Denmark

In the mammary glands, Dieterich found hematopoietic foci which greatly resembled bone marrow. These foci contained mainly cells of the myeloid and the lymphoid series, erythroid elements being rarely found (in one 11 year old child, however, large numbers of erythroblasts were present). Such observations help to confirm the theory advanced by Morawitz and Rehn (quoted by Dieterich) concerning a reciprocal action between the leukocytic and erythroid system. Extramedullary foci were rarely found in the skin of the hand, and never in the skin of the back, head or axilla (Dieterich<sup>6</sup>). Extramedullary foci were never found in the normal adults.

As mentioned previously, the formation of erythrocytes and granulocytes normally takes place in the bone marrow, but this normal formation may be supplemented in pathologic cases by extramedullary blood formation. Such ectopic hematopoiesis frequently takes place in the spleen and the lymph nodes, less frequently in the liver, and only rarely in the suprarenal glands, kidney, cartilages, the broad ligaments, and scattered throughout the adipose tissue of the organism. In general, the sites of extramedullary blood formation which are found normally in embryonic and fetal life, are also the sites in which the phenomenon occurs under pathologic conditions in the infant and adult.

Extramedullary hematopoiesis occurs under various pathologic conditions in adult mammals. Recorded cases refer chiefly to man. In infants and young children, extramedullary hematopoiesis is often found in association with severe anemia.<sup>3</sup> Various authors<sup>4-19</sup> have reviewed the recent literature on ectopic blood formation in erythroblastosis fetalis. In pernicious anemia during relapse, extramedullary hematopoietic foci are regularly found in the spleen and liver.<sup>13-16</sup> In macrocytic anemias, especially those associated with liver disease, such foci are frequently found in the spleen.<sup>21</sup> Extramedullary foci occur in osteosclerosis,<sup>6</sup> in invasion of the bone marrow due to various causes,<sup>3-10,12</sup> and in Hodgkin's disease,<sup>21</sup> even when the anemia is not very severe. Ectopic blood formation has been described in erythremia,<sup>21</sup> hemolytic jaundice,<sup>9</sup> and leukemia.<sup>12</sup> Tumors of heterotopic bone marrow have been observed in adipose tissue of patients with anemia in severe sepsis.<sup>21</sup> Extramedullary hematopoiesis has been produced experimentally by repeated bleeding and by chronic poisoning with blood-destroying substances.<sup>3</sup>

In general, the extramedullary foci may be composed of erythroid elements, myeloid elements, megakaryocytes, or of all three types of cells. The ectopic hematopoiesis is often interpreted as a compensatory phenomenon, evidence for such a theory being, among other things, the readiness with which such a change occurs in infants and young children, in whom the bone marrow has little or no room for expansion.

#### PRESENT INVESTIGATIONS

The present report deals with the results of the examination of a total of 94 individuals, including 79 fetuses from 6 months of age to birth, and 15 children and adults from 1 day to 25 years of age. All fetuses with erythroblastosis fetalis were omitted, and only normal material was used. The material was collected from the Department of Pathological Anatomy, University of Copenhagen.

+ Hematopoietic foci in more than 33% of the fields of vision

(+) Hematopoietic foci in less than 33%, but more than 0% of ten field of vision.

Blank space means no observation made in this case

The organs examined were as follows: mammary glands, liver, spleen, and, in some cases, the suprarenal glands and the soles of the feet. After removal from the body, the organs were fixed in 4 per cent formalin in 0.9 per cent sodium chloride for two days, and then were treated as usual for embedding in paraffin. For each organ 10–12 cuts were taken with intervals of 30  $\mu$ . The 5–6  $\mu$  slides were stained with three different dyes as follows: (1) hematoxylin-eosin, (2) van Gieson Hansen, and (3) May-Grunwald-Giemsa. The sections were examined under the microscope, and a notation made of the presence or absence of foci of hematopoiesis in examination of a number of fields. The particular magnifications used are given below.

As a hematopoietic foci was counted all crowding of cells, which belongs to the hematopoiesis, the cells are usually in different stages of the development. The number of cells varies.

### Results

The results of these investigations are listed in detail in table 1. Certain particulars are listed in tables 2 and 3.

*Liver* It would have been of interest to obtain a measure of the amount of hematopoiesis in the liver, but it was possible to obtain only a relative measure. The

average of foci found per microscopic field using Leitz objective 3-ocular 8, was recorded in the tables. In the liver, hematopoiesis takes place partly within the

lobes (lobular) and partly in the periportal connective tissue (portal) so that it was necessary to make a differentiation between these two groups

The numbers of foci in the livers of fetuses of various ages have been retabulated in table 2. We give here only the maximum and the minimum and the average of the numbers given in table 1

The number of such foci shows a progressive decline with increase in age, and during the last month of pregnancy the amount of hematopoiesis is markedly decreased, as seen in table 2.

*Spleen* In the spleen, the erythroblasts and the myelocytes were counted in the pulp and the follicles, averaging the number found in 10 microscopic fields using Leitz objective 1/12-ocular 8. The results are tabulated in table 3. It will be seen that erythropoiesis in the spleen still takes place at the end of fetal life.

*Mammary glands* In sections of the mammary glands, twenty fields of vision were employed (Leitz objective 3-ocular 8), and the amount of hematopoiesis listed from zero (0) to 3 plus (+++), as explained in table 1.

Although the material was small, it allowed the conclusion that the hematopoiesis was maintained to greater extent in the female than in the male fetuses.

These results agree with earlier investigations<sup>4, 10</sup> that the extramedullary foci occur in relation to the sudorific glands or their modifications, e. g., the mammary glands.

*Prostate* In the prostate, extramedullary hematopoiesis was observed in anatomic relation to the lobules, but the number of foci was not large. The findings confirmed the observations of Schlachta<sup>17</sup> that it is normal to find extramedullary foci here. The same seems to hold true for the mammary glands.

*The sole of the foot* Only a small part of the material was used for these investigations. Here there are small numbers of foci, almost always in relation to the sudorific glands, rarely in the adipose tissue.

*The suprarenal glands* Only a few cases were examined. In them, the extramedullary foci were very small and few in number.

#### COMMENT

These observations on the rather persistent extramedullary hematopoiesis in the mammary and prostatic glands seems to indicate that the immature blood cells find similar conditions in the bone marrow and the stroma of the gland in question. If this is so, an explanation may be forthcoming why malignant epithelial tumors arising in the breast and the prostate metastasize to the bone (in particular, to bone containing active blood-forming marrow). In this connection, it is of interest that extramedullary hematopoietic foci are present during fetal life in the lungs and the kidneys too, and that bronchogenic carcinoma and hypernephroma also very often metastasize to bones.

These statements are offered only as reflections. Further investigations along these lines are in progress.

#### SUMMARY

Investigations of extramedullary foci of hematopoieses demonstrate that, in human beings, the extramedullary hematopoiesis in the fetus at term is more pronounced in the mammary glands of the female than in those of the male. The author suggests the possibility that there may be a connection between the location of the foci, and the liability of metastasis in cancer, especially in mammary and prostatic cancer.

## ACKNOWLEDGMENT

The work was supported by a grant from King Christian the Tenth foundation and the Carlsberg Foundation. I bring my sincere thanks to both these foundations.

\* The riboflavin and pyridoxine series were run earlier than the others, using a somewhat heavier culture suspension this accounts for the greater number of organisms ingested

In every series of rats, deficiency of any one vitamin sufficient to retard growth also caused a reduction in phagocytic activity of the white blood cells. This reduction was most marked in the riboflavin and pyridoxine series in which the rats had been kept on the deficient diets for seven weeks before being tested. In thiamin deficiency of four weeks duration, there was a marked reduction in ingestion rate.

Group differences of 2 or more in the number of bacteria ingested per cell are of

unquestionably mathematical significance in the rat data here set forth. With hot-room groups 1 and 4 of the pyridoxine series, for instance, the difference is 7.67  $\pm$  0.55, the difference being fourteen times its own probable error and with only an infinitesimal likelihood of ever occurring by chance along. Even the difference of 4.11  $\pm$  0.34 (cold-room groups 1 and 3 of the thiamin series) is twelve times its own probable error.

The testing of each series of rats was done in the course of a single half day, using one dilution of the bacterial culture for all tubes. It is conceivable that many of the organisms might have died during the course of the two hours or so elapsing between the running of the first and last groups of the series, thus accounting for the rising ingestion rate. However, no significant difference was found when the culture suspension was tested on normal bloods after standing for intervals up to five hours after the dilution was made, nor did the use of a heat-killed culture alter the rate of ingestion. Furthermore, the order of testing was always to finish the groups of one room and then go on to those of the series in the other room. It is thus not possible to account for any of the observed differences on the basis of change in the culture. The samples of heparinized blood stood about fifteen minutes on the average before being run, but even five hours of standing at room or water-bath temperature had no effect on white cell activity.

We have made no use of continuous observations of phagocytic activity of single cells, since different neutrophils of the same animal may show rather marked variations in activity. The statistical approach seemed more appropriate and has been used throughout. In registering ingestion counts, any cell was considered full when it contained 30 or more bacteria. Beyond this point, accurate counting became impossible because of the crowding.

In the entire absence of any vitamin, phagocytic counts often rose from their usual low level when the condition of the deficient animal became critical. It is to be noted also that our highest ingestion-counts were always obtained in animals receiving the diet richest in the vitamin concerned. Studies are now in progress to see whether this relationship would continue with still higher concentrations of vitamin in the diet.

In addition to the studies shown in table 1, preliminary tests have indicated that lack of vitamins A and D (combined) produces a similar reduction in phagocytic activity. Inositol and p-aminobenzoic acid have so far been found to be without effect.

*Effects of vitamin C deficiency on phagocytosis in guinea pig blood.* Four groups (4 to the group) of young guinea pigs were placed on a basal diet consisting of wheat bran (45 per cent), rolled oats (25 per cent), and dried skimmed milk (30 per cent). Three drops of haliver oil were given weekly to supply vitamins A and D. One group in the hot room and one in the cold were given plenty of leafy vegetables in addition to the basal diet, while the second group in each room got no vitamin C. After three weeks, the weight of those getting no vitamin C showed no gain, as contrasted of an average gain of about 60 grams per pig in the control groups. Phagocytic tests at the end of the 3-week period gave the ingestion findings, as shown in table 2, using the same technic as in the rat studies.

A second series of guinea pigs were kept in the rooms on the basal diet for four weeks. Graded amounts of ascorbic acid were given daily by pipet, these amounts being 0.5 mg, 1.5 mg, and 3.0 mg per day per pig. All those in the cold room receiving no ascorbic acid died near the end of the fourth week before they had been tested for phagocytic activity. Those of the corresponding hot-room group died during the fifth week. Tests on those remaining alive at the end of the fourth week gave the results as shown in table 3.

The guinea pig bloods were highly unsatisfactory to work with because of troublesome clumping and fragmentation of the phagocytic cells. Even with all due reservations as to the accuracy of the counts, however, there is no doubt of a marked reduction in phagocytic activity in severe vitamin C deficiency.

TABLE 2

	Number of bacteria ingested per cell
Cold room full diet	18.30 $\pm$ 0.23
no vitamin C	7.30 $\pm$ 0.30

*Protein deficiency studies in rats* Increasing emphasis is now being placed on the role of body proteins in resistance to infection and on the maintenance of acquired immunity. Cannon's excellent discussion of the subject pictures the loss of protein-attached immune bodies as tissue reserves of protein are depleted from any cause (blood loss, protein starvation, and the malnutrition accompanying vitamin deficiency, debilitating disease or old age). No mention has been made, however, of the part reduced phagocytosis might play in such loss of resistance. Hence, we decided to study this phase of the subject in conjunction with our work on vitamin deficiency and differences in protein requirement in heat and cold.

Using the phagocytic technic and basal diet described in the preceding pages, we adjusted the protein- and sugar content of the basal diet to give 6, 12, 18, 24, and 36 per cent protein and corresponding reductions in sugar. All vitamins were kept at optimal levels, with the needed increases in thiamin and choline in the hot room. Weanling white rats (males) were placed on these diets in the hot and cold rooms in groups of 4. After five and one-half weeks on the diets, the rats were bled and phagocytic tests run as described. The data obtained are as shown in table 4.

Here we see best phagocytosis and best growth taking place at 18 per cent dietary protein in the cold-room rats, with slight growth impairment and marked reduction in phagocytic activity as protein intake is increased above this level. In the hot room, on the other hand, both growth and phagocytic activity continue to improve with rising protein intake, even up to the 36 per cent level. While the differences in phagocytosis between contiguous groups of rats are not mathematically significant, those between the high and low groups of each room are highly so. The difference between groups 1 and 3 of the cold room ( $2.98 \pm 0.37$ ) is eight times its own probable error and would occur by chance only once in 14,700,000 times. Similarly, the difference of  $3.56 \pm 0.39$  for hot-room groups 1 and 5 is nine times its own probable error. Just why phagocytic activity should decline with the higher protein intakes in the cold must be left for future explanation.

TABLE 4

	Protein in diet	Bacteria per cell	Aver wt after 5½ weeks
	%		gm
At 68 F	6	$3.54 \pm 0.22$	70
	12	$3.76 \pm 0.24$	156
	18	$6.52 \pm 0.30$	206
	24	$4.66 \pm 0.21$	205
	36	$3.28 \pm 0.21$	201
At 90-91 F and 60-70% relative humidity	6	$3.76 \pm 0.23$	51
	12	$4.78 \pm 0.24$	100
	18	$5.62 \pm 0.23$	157
	24	$5.39 \pm 0.26$	195
	36	$7.32 \pm 0.32$	203

From these observations it seems evident that protein intake is fully as important as proper vitamin supply in maintaining optimal phagocytic activity. The casein used here as the total protein supply is poor in cystine, but even when 0.2 per cent cystine is added to all diets there still is evidence of a higher protein requirement in the heat than in the cold.

*Time lag in phagocytic response to changes in nutritive state.* Preliminary observations had indicated that full vitamin-deficiency effects on phagocytosis would be in evidence after four weeks on the deficient diets. It seemed desirable, however, to have more definite information on the time relationships involved.

Weanling white rats (Sprague-Dawley males) were placed in tropical warmth (90 to 91 F and 60 to 70 per cent relative humidity) and kept on synthetic diets for eight months before being used for the study. The rats in one group received the optimal diet for tropical warmth described previously, while those in the other group received a diet moderately deficient in protein and all the B vitamins (table 5).

While this low-vitamin rat diet would appear to be only mildly deficient, it was about as low as would be tolerated by 8 month old rats. Further reduction of

thiamine from 12 mg per kilogram down to 10 mg per kilogram resulted in typical severe deficiency symptoms and death within four to five weeks. Rats of this age, kept since weanlings in the heat on the optimal hot-room diet, also develop fatal thiamine deficiency in about the same time if the dietary thiamine is reduced to 10 mg per kilogram.

Using the technic described above, we measured the phagocytic activity of the blood polymorphonuclear neutrophils and then placed the rats with deficiencies

TABLE 5 — *Amounts of B-vitamins and Casein per Kilo of Diet*

on the optimal diet while changing some of the normal rats to the deficient diet. Estimates of phagocytic activity and weight change were made weekly thereafter for each group. Four rats in each group were bled from the heart and discarded from the study at the end of each week so that the study would not be complicated by any possible effect on phagocytosis from repeated bleedings.

In table 6 are set forth the changes in phagocytic activity and body weight which took place from week to week. Even though the dietary shifts in each case were promptly reflected in body weight changes within the first week, no corresponding

alterations were found in activity of the blood phagocytes. By the end of the second week a moderate change was observed in phagocytic function; this became more marked during the third week and was complete by the end of the fourth week (fig 1). After four weeks, the rats that formerly had deficiencies exhibited normal phagocytic activity, while those previously normal were now at the low level of full deficiency.

With bacterial counts made in 40 phagocytes from each rat (making 160 cells for each mean value recorded in the table), differences in one day's readings greater than 15 became statistically significant. Naturally the readings of one week can be compared with those of another week only by reference to each week's normal values obtained on the control rats. The bacterial suspension used in the third week's test was slightly too dilute, while that of the fourth week was distinctly

FIG. 1. Phagocytosis in rat malnutrition and recovery

heavy. This necessitated the calculation of comparative changes on a percentage basis, using the normal controls as 100 per cent in every case. Differences of  $\pm 10$  per cent are of no definite significance here.

One review journal has recently<sup>3</sup> criticised our use of only 40 cells per rat (four rats to each group) as the basis for calculating mean ingestion rates, referring to the custom of counting ingestion from 200 to 500 cells in human phagocytic studies. To test the stability of our ingestion values, we selected two representative groups from our previous report, Groups 1 and 3 of the riboflavin series in the cold room. In addition to the mean values calculated on counts from 160 cells per group (40 per rat), we recalculated the data on the basis of including only the first 20 (10, 5, and 2 phagocytes seen on each slide). In table 7 are set forth the results of this recalculation, and it is clearly indicated that the observed differences in mean ingestion counts maintain their statistical significance when as few as only the first 10 cells per rat are included in the calculation. It may thus safely be accepted as

true that counts made on 40 phagocytes per animal, with four animals to each group, allow an ample margin of stability. In human case studies, 100-cell counts would provide sufficient stability if the technical details of the method were carefully standardized.

TABLE 7

No. cells counted		Group 1		Group 3		Group diff in means	Size of diff in means needed for significance (P.E. X 4)

### DISCUSSION

From the results here presented, it would seem that the ability of bone marrow to produce active phagocytes is dependent on the same nutritional requirements needed for optimal body growth. Deficiency of any one of the B vitamins (except inositol or p-aminobenzoic acid) or of protein sufficient to retard body growth also interferes with the marrow production of normally active phagocytes.

This effect of nutritional deficiency seems to be exerted only upon phagocytes during their early immature period in the marrow tissue, for nutritional correction—which at once restores normal growth—fails to bring back normal phagocytic activity to circulating granulocytes except after a lag of between two and three weeks. It therefore seems justifiable to conclude that granulocytes already in the circulating blood are not influenced by changes in nutritional status, that they are susceptible only during their early formative period. This means that improved phagocytosis cannot be expected until two to three weeks after nutritional faults have been corrected.

Fewer, as well as less active, phagocytes are produced in deficiency states, the total leukocyte counts in rats dropping from a normal level of around 10,000 per cubic millimeter down to about 4,000, without any marked change in the differential count.

Preliminary observations have shown phagocytosis to be 4 to 5 times as active in some human subjects during the summer months than through the winter season. Whether this winter decline in activity is related in a causative way to the greater susceptibility to colds and other respiratory infections, forms interesting grounds for speculation.

### CONCLUSIONS

Deficiency of any of the B-vitamins (except inositol or p-aminobenzoic acid), vitamin C, or of protein, leads to a reduction in phagocytic activity of the blood.

granulocytes in experimental animals. This effect of a faulty diet, or of a restoration to normal after a period of malnutrition, alters the phagocytic activity of circulating granulocytes only after a lag of two to three weeks, thus leading to the conclusion that these cells are susceptible to nutritional faults only during their early formative period in the marrow tissue.

# SOME OBSERVATIONS ON THE EFFECT OF FOLIC ACID ANTAGONISTS ON ACUTE LEUKEMIA AND OTHER FORMS OF INCURABLE CANCER

By SIDNEY FARBER, M D

THE PRODUCTION of temporary remissions in the course of acute leukemia in children by the administration of the compound, 4-aminopteroylglutamic acid (aminopterin)<sup>1, 2</sup>—a biologic antagonist to folic acid\*—has raised a number of theoretic and practical questions. Confirmation of this finding has been reported from several sources<sup>3</sup>, temporary remissions equally impressive have been obtained in adults with acute leukemia by Dameshek.<sup>4</sup>

It is the purpose of this paper to summarize briefly the status of our observations† on the action of folic acid antagonists on acute leukemia and other incurable forms of cancer for the interest of those now working with these agents, to state the nature of some of the problems which have arisen, and to indicate some directions of further research.

The demonstration by Lewisohn and his colleagues<sup>5</sup> of the occurrence of complete regression in about one-third of single spontaneous breast cancers in three different strains of mice treated with fermentation L casei factor, later shown to be pteroyltriglutamic acid (Hutchings et al.<sup>6</sup>) and the subsequent synthesis of this compound by SubbaRow and his co-workers<sup>7</sup> led to our study of the effect of pteroyltriglutamic acid on incurable cancer in man. Among the patients so treated were 11 children with acute leukemia. The occurrence of what we called an acceleration phenomenon in the viscera and bone marrow of these patients and an experience with folic acid deficiency experimentally produced in the rat suggested that it would be worth while to ascertain if this acceleration phenomenon might be employed to advantage in the treatment of acute leukemia in children, either by the use of radiation or nitrogen mustard therapy after pretreatment with folic acid or conjugates of folic acid, or by the immediate use of folic acid inhibitors or

Presented in part at the Congress of the International Society of Hematology, Buffalo, New York, August 25, 1948.

This study has been supported in part by Cancer Grant #250-390 of the National Cancer Institute, United States Public Health Service and in part by The Children's Cancer Research Foundation, Boston.

This paper is dedicated to Dr. George R. Minot. It was my privilege when a student to hear his lectures on diseases of the blood. In these he united in masterful fashion the fields of pathology, physiology, and clinical medicine to establish a logical approach to the nature of disease and so in therapy. His announcement, when I was a fourth year student, of the liver treatment of pernicious anemia fired the imagination of all who heard him to a consideration of the role of nutrition in other incurable diseases of unknown etiology. S. F.

\* By antagonist to folic acid is meant a substance which possesses the property of inhibiting the growth of *Streptococcus Faecalis R.* or *L. casei* in the presence of marginal levels of folic acid. Reversal of inhibition occurs when the concentration of folic acid in the culture medium is elevated.

† Our studies represent the accomplishment of a group of clinicians and laboratory workers who have joined forces to make possible rapid progress along the lines indicated in this paper. Detailed reports of clinical, experimental, toxicologic and pathologic studies are being prepared for publication.

antagonists \* The first folic acid antagonists—pteroylaspatic acid and methyl pterotic acid—were effective enough not only to give the needed encouragement for further research in this direction, but also to prolong the lives of a few children with acute leukemia until more powerful antagonists of folic acid were made available The first impressive remissions in the course of acute leukemia were produced by the use of aminopterin beginning in November of 1947 These were characterized by a return almost to a normal state in some and to a state almost indistinguishable from normal in others in a group of 10 of 16 children with acute leukemia The toxicity of aminopterin emphasized the need for less toxic compounds which it was hoped might be even more effective in their carcinolytic action<sup>1,2</sup>

### *Compounds Related to Aminopterin*

Observations have been made on children with acute leukemia and on patients with a variety of other forms of incurable cancer treated by two compounds closely related to aminopterin Both of these were supplied by the late Dr Y SubbaRow These are 4-aminopteroylglutamic acid (amethopterin) and 4-aminoaspatic acid (amino-an-fol) \* A complete account of these studies will be presented elsewhere In general it may be stated that while amethopterin and amino an fol are less toxic than aminopterin, exactly the same toxic changes may be produced when appropriate doses are employed This holds true for laboratory animals and for man Remissions in the course of acute leukemia in children equal to those produced by aminopterin may be brought about by the use of amethopterin or amino an fol The effective dose when remissions are obtained in children with acute leukemia lies between 3 to 5 mg a day for amethopterin, and between 25–30 mg a day for amino an-fol, depending upon age, weight, size, and physical condition of the patient These figures may be compared with a range of 0.5 mg to 1.0 mg a day of aminopterin Because there is some differential in the dose required to produce toxic changes, as compared to the effective dose, it has been possible to shift from one drug to another when early signs of toxicity have become apparent

### *Pattern of Therapy*

It is impossible to present at this time a pattern of therapy as definite as that governing the use of digitalis, for example, or insulin Daily white count and physical examination are the best guides to the treatment to be given that day Too rapid a drop in the white count, diarrhea of unknown origin, the presence of stomatitis, a sore tongue, or ulceration of the mucous membranes of the mouth,

\* Acknowledgement is made to the late Dr Y SubbaRow and his colleagues in the Research Division of the Lederle Laboratories (American Cyanamid Company) and their associates of the Calco Chemical Division, who are responsible for the chemical research that made possible these studies on children A particular word of gratitude is expressed not only for the invaluable chemical contributions of Dr SubbaRow but also for his decision to pursue so effectively by further chemical research the leads which were obtained from these studies on children with acute leukemia The present plan of study concerning the action of folic acid antagonists is following along the lines decided with Dr SubbaRow in the spring of 1947 It consists essentially of the study of the action on laboratory animals and on patients with various forms of incurable cancer of related compounds in an attempt to find one which is more effective and less toxic than any we have previously employed

should serve as reasons for cessation of therapy until the exact cause for these disturbances has been determined. In periods of remissions treatment continues as before, although slightly smaller doses may be administered. In some instances when patients are doing well, intramuscular injection of the compound employed has been given on every other day. Aminopterin apparently is effective also when given by mouth.

### *Toxicity*

Our initial report carried a warning concerning the toxic nature of aminopterin. Stomatitis, ulceration of the mucous membrane of the mouth, smooth tongue, pharyngitis, and atrophic changes in the intestinal epithelium of the type produced by folic acid deficiency in the rat and in the monkey, diarrhea, gastro-intestinal hemorrhage, particularly when there is diffuse leukemic infiltration of the bowel, and depletion of the bone marrow leading to aplasia are the most important changes. Despite efforts to prevent or to overcome quickly the toxic manifestations by the use of liver extract, various vitamin B preparations and folic acid itself in doses up to 200 mg. a day for several days, the most effective treatment appears to be suspension of administration of aminopterin for four to seven days at the first sign of stomatitis or diarrhea of unexplained origin.

The occurrence of hypersegmented polymorphonuclear leukocytes and the presence in the bone marrow of megaloblasts have been observed as important evidences of the effect of the antagonist. It is impossible to state at this time with certainty whether all of the changes produced in acute leukemia by antagonists to folic acids are manifestations simply of a folic acid deficiency. It does appear that the alterations are at the same time more profound and more subtle than those produced by folic acid deficiency alone and that interference with biochemical systems more important than simple competitive substitution of the antagonist for folic acid within cells must obtain. Evidence bearing on this point is being collected.

### *Hemorrhage*

Hemorrhage into the gastro-intestinal tract, the skin, and the genito urinary tract and the cranial vault, either massive or oozing in character, has always been one of the most serious complications of acute leukemia and one of the important causes of death. Studies now being conducted by our group following the work of Allen and Jacobsen<sup>9</sup> show that in many children with acute leukemia the level of heparin-like substances in the blood is definitely higher than the normal. While bleeding occurs usually when the level of blood platelets is low, thrombocytopenia may be present without any evidence of bleeding for many months. The longer survival of patients with acute leukemia made possible by folic acid antagonist therapy has brought the problem of hemorrhage into great prominence. The combination of leukemic infiltration of the intestinal tract and toxic effects produced by aminopterin, amethopterin, and amino-an-fol makes for the ready occurrence of gastro-intestinal hemorrhage. Although the exact explanation is not clear it appears certain that hemorrhage occurs more readily if the bone marrow is markedly depressed by the compound employed. The effect may be similar to that of

duced in aplastic anemia where gastro-intestinal hemorrhage is a common and serious occurrence. If toxic levels of the folic acid antagonist are employed long enough, the bone marrow may be depressed enough to accentuate the hemorrhagic tendency in leukemia, or to act as the sole cause of the hemorrhage.

### *Nature of Leukemia*

Observations on a girl (M. D.), 8 $\frac{1}{2}$  years old at the time of her death, and similar experiences with other children have raised a question concerning present conceptions of leukemia. This child lived for twenty-two months after the onset of acute leukemia. Treatment with pteroylaspartic and methylpterotic acid was followed by repeated temporary periods of improvement. She died following uncontrollable oozing from the mucous membranes. Postmortem examination revealed leukemic cells so few in number, in scattered areas throughout the body that the diagnosis of acute leukemia would have been made with hesitation on the basis of that evidence alone. It seems probable that hemorrhage in acute leukemia may be produced by a number of different factors apart from the effect of leukemic infiltrates on the bone marrow and viscera and the thrombocytopenia. The hypothesis seems warranted, that a serious disturbance in the hematopoietic system, or a series of deficiencies in the body responsible for oozing or for massive hemorrhage might still be present in the patient with acute leukemia if every leukemic cell in the body could be destroyed. Acute leukemia, therefore, may be a form of cancer complicated by specific deficiency states—a suggestion that has definite implications for further research.

### *Types of Leukemia*

In the majority of the children with acute leukemia treated it was impossible to diagnose with certainty the exact morphologic type of leukemia because of the primitive nature of the blasts. It would seem logical, and certainly highly desirable to replace or to supplement the morphologic classification of leukemia by one based upon response to specific stimuli, such as the folic acid antagonists. Study of those patients with acute leukemia who failed to respond to these compounds might yield data of value concerning the nature of the disease. A worthy goal is the characterization of the various types of acute leukemia in terms of precise intracellular biochemical deficiencies or alterations.

### RESULTS

In a group of approximately 60 children with acute leukemia treated for three weeks or longer with either aminopterin, amethopterin, or amino-an fol, some what more than 50 per cent showed improvement clinically, hematologically of important degree attributable to the action of these compounds. Detailed tabulations of our entire experience with thorough documentation will appear separately. Two of the five children whose case histories were presented in our initial report are still alive (December 21, 1948). Case 1 of that report, a boy of 8, has a history of acute leukemia beginning in February 1947. He was treated first with methylpterotic acid and pteroylaspartic acid. Aminopterin was not given until December

16, 1947 Since then that, or one of the other more powerful folic acid antagonists have been employed Leukemia is still present and there have been many complications, but he is still alive twenty-three months after the onset of his disease A second child mentioned in the earlier report, Case 5, has had acute leukemia since August, 1947 He is one of twins and despite his leukemia and almost constant folic acid therapy, he is as tall and as well nourished as his brother His leukemia, which is still recognizable by studies of bone marrow and peripheral blood, is still under control sixteen months after onset

The widespread use today of aminopterin in the treatment of acute leukemia has raised for discussion a basis of comparison of results Any evaluation of treatment of patients with incurable cancer must rest upon a solid foundation of knowledge concerning the life history and biologic behavior of tumors Acute leukemia, which runs an invariably fatal course, varying from a few weeks usually to six months after onset of symptoms, lends itself readily to comparative studies Rarely the course may last as long as twelve months, and isolated instances of longer survivals have been observed The end point of time itself, therefore, should serve as a reliable criterion of the value of any form of therapy

Spontaneous remissions, either complete or partial, occurred in 10 per cent of 300 children with acute leukemia observed by Dr Louis K Diamond,<sup>10</sup> at the Boston Children's Hospital These averaged slightly less than ten weeks in duration In two instances a second remission was observed In almost 75 per cent of these children in whom spontaneous remission was noted, there was a history of infection of important degree immediately preceding the remission The recent production of remission in acute leukemia by the use of massive blood transfusion makes necessary the evaluation of this factor too, in patients treated with folic acid antagonists Analysis of our experience permits the statement that the remissions we have described are dependent neither upon infection nor transfusions of blood

It is obvious that no two children with acute leukemia present strictly comparable problems Infiltration of the leukemic processes is generalized but there are great variations in the degree and site of involvement In one, a large subdural accumulation of tumor may alter intracranial pressures to an important degree, in another, the leukemic infiltration in the heart may be responsible for unexpected death Other variables are the amount of replacement of the bone marrow by leukemic cells, the factors responsible for bleeding, and the occurrence of secondary infections It should not be surprising, therefore, if one research group reports five consecutive remissions (personal communication from Dr George Guest, Cincinnati Children's Hospital), or that another group observes a fatal outcome within two weeks after onset of therapy in ten consecutive patients before one remission is observed The arbitrary limit of three weeks after onset of therapy has been chosen for a basis of comparison During this period those patients most severely involved will have died or the folic acid antagonists employed will have had an opportunity to effect the tumor infiltrations in the viscera and the bone marrow

It should be emphasized that all available resources of medicine have been utilized in an attempt to prolong the lives of our patients with acute leukemia Transfusions, radiation therapy, antibiotics and specialized dietary measures have all been

employed when indicated. It has been possible, however, to study a sufficient number of patients for long enough periods of time with folic acid therapy alone to permit the accumulation of sufficient data upon which reliable conclusions could be based. *It should be expected, therefore, that considerable variation in the results of different investigators will be reported until a sufficiently large experience has been obtained, or until a long enough period has elapsed to permit the use of the period of survival alone as the simplest criterion of therapeutic effect.*

The effect of these folic acid antagonists, despite some theoretic considerations which entered into the formulation of early working hypotheses, is not limited to acute leukemia. We have reported<sup>11</sup> temporary, definite but inconstant carcinolytic action on patients with apparently unrelated forms of incurable cancer, such as neuroblastoma, and pulmonary metastases from cancer of the bladder, as well as more closely related tumors such as lymphosarcoma and Hodgkin's disease.

The range of carcinolytic action on various types of incurable cancer in man is now being evaluated. The combined action of the folic acid antagonists when employed with other agents used in the treatment of cancer, such as the sex hormones and radiation therapy is under study.

The toxic nature of the compounds employed in these studies and the inconstant and temporary nature of beneficial effects make clear that the value of these compounds is still limited to research. The finding of equally or more effective and less toxic compounds, and an understanding of the reasons for failure in those patients who do not respond are goals which must be reached before more widespread application of the results of these studies is possible.

#### SUMMARY

A general discussion is presented of the present status of folic acid antagonist therapy in acute leukemia in children and in other forms of incurable cancer. Conclusions reached in our initial report have been supported by a far greater experience. Temporary remissions in acute leukemia as marked as those caused by aminopterin have been produced by the use of two compounds closely related chemically to aminopterin—amethopterin and amino-an-fol, both of which, however, are also toxic compounds. Despite the increasing number of patients in whom temporary remissions have been produced, with survival in some far beyond the usual course of the disease, no evidence has been presented which would justify the use of the word "cure" of acute leukemia. A carcinolytic action on related and on certain unrelated forms of incurable cancer has been observed. Further research for less toxic related compounds with even greater effectiveness is not only justified by these studies but is imperative. The value of this direction of research in cancer has been established.

Two of the most pressing problems demanding solution are concerned with the nature, the prevention, and the treatment of toxic changes, including hemorrhage, produced by these folic acid antagonists and the causes, prevention and mechanism of hemorrhage in acute leukemia. The use of the folic acid antagonists in the treatment of incurable cancer including leukemia must remain in the realm of research until answers to these questions are found.

# THE USE OF FOLIC ACID ANTAGONISTS IN THE TREATMENT OF ACUTE AND SUBACUTE LEUKEMIA

## A PRELIMINARY STATEMENT

By WILLIAM DAMESHEK, M D

A RECENT meeting of the New York Society of Hematology held on November 30, 1948, was devoted to a symposium on the treatment of leukemia with aminopterin. It was obvious that definite remissions induced by the drug and not of spontaneous nature were being obtained, although the results of therapy in the hands of various workers differed considerably.

In this issue Farber presents a summary of his results with various folic acid antagonists. Since Farber's observations deal almost wholly with children and our own work has been almost wholly with adults, it was thought that a preliminary statement of our own results with these drugs as reported at the above meeting might be of interest.

Thirty five cases of acute and subacute leukemia including 4 children and thirty one adults, are or have been under treatment with one or more of the folic acid antagonists since mid-April 1948.\*

The folic acid antagonists used were 4 amino, pteroyl glutamic acid—(aminopterin), 4 amino, N<sup>10</sup> methyl pteroyl glutamic acid (a-methopterin), 4 amino, pteroyl aspartic acid—(amino-an-fol), and 4 amino, 9 methyl pteroyl glutamic acid—(a-ninopterin).

These chemicals, dissolved in sterile normal saline, were injected intramuscularly daily until a toxic or pronounced hematologic reaction occurred, following which the drug was discontinued. The drug was then resumed in a maintenance dose when the toxic reaction had subsided. Aminopterin was given in a dosage of 1-4 mg daily, a-methopterin, 2-5 mg daily, amino-an-fol 25-75 mg daily, and a-ninopterin 5-15 mg daily. Maintenance therapy was given either daily or every other day and either by intramuscular or oral route. Tablets of oral aminopterin were ordinarily used in 1 mg dosage.

Of the 35 cases of acute and subacute leukemia, 1 has been under treatment for less than four weeks, leaving 34 cases for analysis. Of these, 8 died within one to five days after therapy was instituted. Since death occurred so shortly after institution of drug therapy, these cases should probably be excluded from any statistical analysis of the therapeutic effects of the drug. If this is done, 26 cases of acute and

From the Ziskind Laboratories (Hematology Section) of the J. H. Pratt Diagnostic Hospital and the Department of Medicine Tufts College Medical School. Aided by Grants from the American Cancer Society (Massachusetts Division), the Charlton Fund and the Lederle Laboratories. A detailed report of our findings is in preparation.

\* The detailed data obtained in these cases will be presented by Drs. William Dameshek, Milton Freedman and Lester Steinberg at a later date.

subacute leukemia are left for evaluation. Of these cases, 9 have had continued or intermittent remissions for at least two months and up to eight and one-half months (as of January 20, 1949). A remission is deemed present when the patient, (a) feels subjectively improved, (b) shows such objective clinical improvement as regression of lymphadenopathy and hepatosplenomegaly and loss of hemorrhagic tendency, (c) shows hematologic improvement as evidenced by improvement in the red cell count, return of leukocyte counts to relatively normal values, a definite increase in blood platelets, and an improvement in the marrow picture, and (d) shows continuous improvement for at least two months.

The remission rates are, therefore *Gross results* 34 cases (8 dying in one to five days), 9 remissions = 26 per cent. *Adjusted results* 26 cases (excluding those dying in one to five days), 9 remissions = 34 per cent.

In the early stages of the study, crude liver extract was used in the attempt to allay the toxic symptoms but this was soon discarded. Folic acid was also used in one case, but since it caused a quick relapse in the leukemic process, it was discarded after a single trial. Penicillin was given routinely in the presence of marked granulocytopenia and/or fever. Transfusions of blood were used to maintain the red cell count at levels of approximately 2.5 to 3.0 M.

The remissions occurring in the 26 cases cited above were further analyzed with respect to the proliferating cell type involved. This is often very difficult because of the primitiveness of the proliferative process. In the more recently studied cases, a battery of studies were carried out to determine this previously rather academic question. This included not only the use of the ordinary Romanowsky stains, but oxidase stains, supravital studies, histochemical staining methods including the use of sudan black and phase microscopy.

Best results with the folic acid antagonists were obtained in the lymphoblastic cases. None of the monocytic cases responded.

	Cases	Remissions
Lymphoblastic	10	5
Myeloblastic	9	3
Monocytic	3	0
Unclassified	4	1

The greater specificity of the folic acid antagonists for lymphoblastic proliferations is in line with a more or less marked specificity of certain of the chemotherapeutic agents now in use for certain cell types. Thus, nitrogen mustard appears to be most useful in reticulum cell proliferations including Hodgkin's disease, reticulum cell sarcoma, and reticulosis, urethane in granulocytic proliferation of the chronic myelocytic type and in plasmacytoma (multiple myeloma).

Following the development and then subsidence of the toxic reaction to the drug or following the appearance of a reasonably normal white blood cell count, or under both circumstances, a maintenance dose of the drug was given. In recent months, this was usually given by oral route, in a dosage of 1 mg daily or every other day. Oral aminopterin has proved to be equally as effective as the parenteral medication, causing as marked therapeutic and toxic effects, mg for mg, as when given parenterally.

Toxic reactions were the rule with aminopterin administration. These depended in great part on the dose used and were in the nature of ulcerative mucous membrane and tongue lesions, nausea, burning sensation in the upper abdomen and diarrhea, a form of vascular purpura and an apparent aggravation of the bleeding tendency.\* The marked reduction in leukocyte count and to lesser extent of the other blood elements might be considered as due to a preferential effect of the chemical on the bone marrow. Other folic acid antagonists, such as  $\alpha$ -methopterin and amino-an-fol were less toxic than aminopterin but in general of lesser therapeutic value.

The impression was obtained that in order to obtain a remission it was necessary to bring about definite so-called toxic manifestations. The margin of safety between a toxic reaction and death was at times very small.

It is the natural objective of the chemist to produce materials with relatively slight degrees of toxicity while maintaining at least a standard therapeutic effect. Recent observations indicate that such a possibility may be present in one of the methylated aminopterins (9 methyl, 4 amino PGA or  $\alpha$ -ninopterin). In at least one case given this material, therapeutic effects comparable with those of aminopterin were obtained with only minimal toxic effects.

#### SUMMARY

In summary, the folic acid antagonists have, in varying degrees, the capacity to induce remissions in about one third of the cases of acute and subacute leukemia, in adults as well as in children, and in both leukemic and leukopenic forms.

Clinical, hematologic and (to lesser extent) marrow remissions, are obtained most commonly in the lymphoblastic types, least often in the monocytic types.

It is possible that folic acid is required by the primitive white cell as a growth factor. The folic acid antagonists, which resemble folic acid so strikingly in chemical structure, may result in cell death by modifying various enzyme systems within the primitive cells.

Both clinical and hematologic observations indicate that the proliferative process is by no means cured with aminopterin treatment. Acute leukemia may be likened to wildfire which, although damped by aminopterin, continues to smolder. This smoldering may suddenly light up again into an active leukemic picture, unless continued maintenance therapy is given. Despite maintenance therapy, there finally comes a point in the leukemic process at which both the leukemia and increasing toxicity to drug make further progress impossible, and the patient dies.

Other growth factors or enzymes are probably of at least as great an importance as PGA in the metabolism of the primitive white cells and when these are discovered and their antagonists synthesized, the therapeutic results in acute leukemia may be of more consistent and durable nature. It should be realized further that chemotherapeutic methods against leukemia and the leukocytic proliferations in general (and, in fact, against all proliferative disease) are at least in their very

\* A toxic reaction may represent simply one or another aspect of the therapeutic response or the part of cells in various parts of the body to the folic acid antagonist. Tissues differ widely in their response to the chemical and leukemic tissue may be preferentially affected.

infancy The results thus far obtained in acute leukemia, although to large extent disappointing, indicate that well defined remissions can be secured in about a third of the cases For a disease such as acute leukemia, in which remissions previously were highly unusual and of sporadic nature, this indicates a well-defined therapeutic advance and a need for continued investigation along the same general lines

Differences in results obtained by various groups of workers are difficult to explain Several points may nevertheless be considered some of the workers have given inadequate dosage of drug or have failed to use maintenance therapy, some have given folic acid in conjunction with anti-folic acid therapy, in some cases, a crude folic acid antagonist was used, and it is possible that some cases were not observed as minutely as seems necessary An important factor, which can be determined only by the study of a large group of cases, is the natural variability of acute leukemia from case to case We have the impression that our best results are obtained in the relatively subacute cases The fulminating cases, with rapid onset of bleeding and a quick downhill course, are only slightly affected

# THE DISTRIBUTION CURVE OF ERYTHROCYTE FRAGILITY

## A DIFFERENT METHOD OF PRESENTATION OF FRAGILITY OF ERYTHROCYTES TO HYPOTONIC SALINE, WITH PRELIMINARY REMARKS ON THE FUNCTION OF RETICULOCYTES

By J H BOLTON M D

### INTRODUCTION

FOLLOWING Haden's<sup>10</sup> demonstration of the close correlation between spherocytosis and the fragility of erythrocytes to hypotonic saline, Dameshek and Miller<sup>5</sup> postulated that spherocytosis was a preliminary stage in the destruction of the red cell, i.e., partial hemolysis. They were able to show experimentally that the degree of spherocytosis was related to the concentration of hemolysins in the blood and that this was also correlated with fragility. They also described cases of acquired hemolytic anemias with spherocytosis and increased fragility, thus emphasising the danger of using spherocytosis and increased fragility as criteria for the diagnosis of familial acholuric jaundice. In addition, they demonstrated the presence of hemolysins in a number of cases of hemolytic anemia.<sup>6, 7, 8</sup>

The chain of reasoning is that hemolysins may lead to partial damage to the cell, this is followed by entry of fluid and loss of the biconcave disc form with approximation to a spherical shape. Fluid can enter a cell to a certain maximal degree, but if this is exceeded, the cell will rupture. Hence, if a cell is already partially spherical, it will rupture with a smaller entry of fluid than if it possesses the biconcave disc form. As the cell acts as an osmometer, the amount of fluid entering the cell will depend on the concentration of electrolytes on either side of the membrane, and this forms the basis of the fragility test with hypotonic saline.

### METHOD

As usually presented, the fragility curve is sigmoid in shape and alteration of form is difficult to assess. But this sigmoid shape is due to the fact that the curve is a composite one and at each decreasing concentration of saline the percentage hemolysis at any particular point is the sum of all the hemolysis which has occurred at higher concentrations of saline, plus the actual hemolysis occurring at that point. The curve is, in fact, a cumulative curve—known statistically as an *ogive*.

This being so, we can readily convert our findings in any case to indicate what degree of hemolysis occurs at any particular saline concentration.

All that is necessary is to deduct from the percentage hemolysis occurring at any particular level, that which occurred at the immediately higher concentration, and this will give the percentage hemolysis occurring in the range of saline concentration between these two points.

From the Royal Melbourne Hospital Melbourne, Victoria Australia.

The normal range of fragility as given by Creed<sup>2</sup> is shown in table 1 with its conversion to the derived curve. This is shown graphically in figure 1.

TABLE 1

Percentage of saline	0.28	0.32	0.36	0.40	0.44
Total maximal percentage of cells hemolyzed	100	98	90	46	10
Total minimal percentage of cells hemolyzed	98	90	45	10	0

Average saline concentration %	0.26	0.30	0.34	0.38	0.42	0.46
Maximal percentage of cells hemolyzed	0	2	8	44	36	10
Minimal percentage of cells hemolyzed	2	8	45	35	10	0

FIG. 1. Usual representation of normal range of fragility as sigmoid curves and the derived curves (dotted) of the distribution of red cell fragility.

The grouping is rather coarse but it will be seen that the two derived curves are very similar in form to that found in a Price-Jones curve.

If fragility were directly related to spherocytosis and spherocytosis only, this derived curve could be considered to be that of the distribution of cells in terms of their degree of spherocytosis, i.e., a curve directly comparable with a Price-Jones curve of diameter. Unfortunately, as pointed out by Ponder,<sup>18</sup> the red cell does

not act as a perfect osmometer, its degree of perfection in this respect being reduced by decrease in the tonicity of its environment. This is the probable explanation of the skewness of the curves shown for the normal distribution of hemolysis

FIG. 2. Fragility distribution in a case of familial acholuric jaundice before and after splenectomy compared with the normal (dotted)

FIG. 3. Fragility distribution in a case of familial acholuric jaundice reported by Whitby and Hynes

#### APPLICATION TO CASES OF ANEMIA

Derived curves were calculated for various types of anemia

Figure 2 shows the findings in a case of familial acholuric jaundice before and after splenectomy. It will be noted that after splenectomy a smooth curve is obtained, abnormal in that its single mode occurs at a higher concentration of saline than normal. Before splenectomy the curve is not completely smooth but shows a second mode at a saline concentration of 0.65 per cent. This bimodal curve is seen again in a case described by Whitby and Hynes<sup>19</sup> (fig. 3) and suggests

that the cells are not homogenous but are composed of two populations of differing susceptibility to hypotonic saline

This aspect is further emphasised in a case of hypersplenism (fig 4) where we find, as might be expected, a maximal normal mode, but in addition, a marked secondary mode at a concentration of 0.45 per cent saline—a decidedly bimodal curve. Further examination of this curve shows that the abnormal peak involves

FIG 4 Fragility distribution in a case of congestive hypersplenism demonstrating marked bimodality

TABLE 2

Case	Hemolysis due to secondary mode	Reticulocyte
	%	%
R. & P		
D <sub>1</sub>	8	5.4
D <sub>2</sub>	7	16.0
R. <sub>2</sub>	5	9.6
M. <sub>1</sub>	20	26.0
D <sub>1</sub>	6	23.4
B <sub>1</sub>	10	11.0
B <sub>U</sub>	50	30.0
C. <sub>1</sub>	10	6.0
C. <sub>2</sub>	10	9.6
R. <sub>1</sub>	0	0.0
N	0	0.0
	0	0.0

some 30 per cent of the cells and this corresponds to the reticulocyte level at that time

Examination of other biphasic curves shows a similar correlation between the height of the secondary mode and the reticulocyte level. The correlation is even closer if, instead of taking the height of the secondary mode, we calculate the percentage of cells involved in that mode. This can be done only approximately, but gives a rank correlation of 0.67 per cent.

A case of acute hemolytic anemia reported by Ross and Paegel<sup>16</sup> is interesting

in that it shows three modes (fig 5) Reticulocyte counts and spherocyte counts were obtained on the same day, and their percentage corresponds roughly with the percentage of hemolysis involved in each particular modal area

A similar curve can be derived from the results of Goldbloom and Gottlieb,<sup>9</sup> who were investigating normal umbilical cord blood By examination of the residual cells after hemolysis, they showed that the early peak corresponded to disappearance of reticulocytes and the middle peak to destruction of nucleated red cells

FIG 5 Fragility distribution in a case of acute haemolytic anaemia following sulphadiazine sensitization reported by Ross and Paegel Note the three separate modes during the attack and the single mode on recovery

TABLE 3

Reticulocytes	5.4%	Early mode	8%
Spherocytes	46.8%	Middle mode	40%

### DISCUSSION

Erythrocyte fragility has been expressed in different ways by different authors. It may be expressed as the range of saline concentration within which hemolysis occurs and notice may be taken particularly of the point where hemolysis is first seen—minimal fragility—or the point where hemolysis is complete—maximal fragility.<sup>13</sup> More commonly it is shown by means of a diagram relating percentage hemolysis to percentage of saline as previously described. All these methods are open to the criticism that they deal only with the extreme variability of the phenomena and pay little attention to the form of variation.

Various attempts have been made to obtain a single expression for fragility and the most satisfactory discussion on the subject is that of Janet Vaughan.<sup>14</sup> She used the median as her descriptive statistic and recognized that the sigmoid curve was an integral of cell fragility at specific levels. Unfortunately, she assumed that the curve was normal in type and on this basis attempted to express the variability as the slope (b) of the regression line of hemolysis (in terms of the standard deviation from the median) on saline concentration. Extreme values were neglected and

not surprisingly, she found this second statistic of little practical importance. A similar approach was used by Hunter,<sup>11</sup> who also realized that more than one maximum might be found, but was unable to explain this. His methods were used by Parpart et al.,<sup>14</sup> but uncritically in that a 'normal' curve was assumed.

From the previous results it will be seen that the curve of fragility is unlikely to be normal and in pathologic conditions frequently shows two or more modes. In the presence of such irregular curves the use of mean, median, or range, can lead to very erroneous conclusions and the advantage of the suggested method of presentation is that it permits the form of the distribution to be determined before using any statistic to describe position.

The apparent relationship between secondary modes and reticulocytes does not necessarily mean that reticulocytes are more fragile than normal. The presence of reticulocytes may only indicate increased marrow activity and this may be associated with the production of abnormally fragile cells quite apart from reticulocytes.

The literature on the subject of reticulocyte fragility is confusing, it being variously alleged that reticulocytes are less fragile, equally fragile and more fragile than normal.

That young cells are more fragile than normal appears to have been conclusively demonstrated by Cruz et al.<sup>2</sup> They used dogs rendered anemic by bleeding and tagged transfused red cells with radioactive iron so that their age could be followed. A marked difference in the fragility between young and old cells was found and this difference was maintained for five days. Thereafter the fragility of the old and the new cells became virtually identical. Reticulocyte counts were not done so that no further conclusions can be drawn with regard to these particular cells.

Key<sup>12</sup> concluded from his work that reticulocytes were normally fragile. He used rabbits as an experimental animal and emphasized the difficulty in performing reticulocyte counts after partial hemolysis. He pointed out that 'ghost' cells would still retain their reticulum which would stain and cause confusion in counting and also noted the danger of counting only the sedimented cells at the bottom of the tube. If this were done reticulocytes would appear to be more resistant than normal, but if samples were taken from the bottom of the tube and from the cells floating free in the plasma no constant differences could be obtained. This technique is not well described but, from the above description appears to be inadequate.

Swjatskaja<sup>17</sup> concluded that reticulocytes were less resistant than normal but his views were based on an apparent correlation between reticulocyte counts in the peripheral blood of anemic dogs and changes in the fragility of the cells. Residual cells were not examined for reticulocytes and his curves do not correlate accurately in time. The increase in resistance could have been due to the presence of target cells which, according to Bohrod<sup>1</sup> appear shortly after hemorrhage and are more resistant to hypotonic saline.

The most thorough examination of the problem was performed by Goldbloom and Gortlieb<sup>9</sup> who did reticulocyte counts and further fragility tests on the residual cells in each tube after a fragility estimation. Their work was performed on normal infant's blood from the umbilical cord and their conclusion was that reticulocytes were more fragile than normal.

Further work on this point is indicated.

In the application of these curves to actual cases of anemia, it would appear possible to decide whether an apparent increase in fragility was due to the result of an active bone marrow with the production of more fragile cells or to an intrinsic defect in some or all of the cells present. In this way the test should become enhanced in its diagnostic value.

## SUMMARY

- 1 A simple method of representing erythrocyte fragility as a distribution curve of actual cellular fragility is described
- 2 The importance of deciding the form of a distribution before using summarizing statistics is emphasized
- 3 The danger of concluding that abnormal fragility is present in the presence of increased marrow activity is pointed out
- 4 Possible applications in diagnosis are suggested

# THE LABORATORY DIAGNOSIS OF SICKLE CELL ANEMIA WITH SPECIAL REFERENCE TO THE DIAGNOSTIC PARAMETER

By HERBERT M. PERR, M.D.

## INTRODUCTORY REMARKS

SICKLE cell anemia has been recognized as a specific entity since 1910 when it was described by Herrick.<sup>18</sup> Within thirteen years, 18 cases had been reported in the literature, and the clinical and hematologic characteristics had been almost completely described. This disease, defined as a hereditary, familial, acute and chronic hemolytic anemia,<sup>20, 21</sup> occurs predominantly in the Negro race,<sup>6, 13, 20, 23, 26</sup> and is one in which abnormally-shaped elongated erythrocytes can be demonstrated in vitro in the blood. This disease occurs in 0.18 per cent of the Negro population. The problem of early diagnosis assumes greater importance since it has been estimated that there may be as many as 135,000 cases of sickle cell anemia in this country.<sup>25</sup> It is also possible to artificially induce the presence of meniscocytosis,<sup>22</sup> drepanocytosis,<sup>14, 15</sup> and sickling in as many as 4-14 per cent<sup>4, 7, 12, 14, 16</sup> of Negroes tested without the presence of active sickle cell anemia. The etiology of this disease, transmitted as a Mendelian dominant, has not been satisfactorily explained. It is felt that the character of the erythrocyte<sup>25</sup> renders it more susceptible to hemolysis, and in great part, the clinical and pathologic changes are indicative of this process. In most cases, the diagnosis is obvious, but since sickle cell anemia can mimic rheumatic fever, other hemolytic anemias, polyarthritides, osteomyelitis, typhoid fever, pericarditis, catarrhal jaundice, meningitis, peptic ulcer, appendicitis, cholecystitis and other acute surgical abdominal conditions, the diagnosis in some cases depends upon adequate laboratory procedures.<sup>3, 6, 8</sup>

Until recently, the in vitro demonstration of sickled cells was considered the sole pathognomonic evidence of the trait. It was an early finding that the erythrocytes in a drop of capillary blood sealed from the air between a glass slide and a cover slip by liquid petrolatum<sup>10</sup> underwent progressive changes from the normal biconcave disc through various stellate and spiculated forms to a thin elongated type that resembled sickles.<sup>17</sup> Most workers agreed that the changes were due to the progressive oxygen unsaturation with the formation of reduced hemoglobin in the preparation.<sup>15, 25</sup> While it was possible to produce sickling in sealed preparations, this trait was frequently absent in simultaneous preparations of the same blood.<sup>1, 11</sup> In 1928, Hahn<sup>14</sup> noted that the formation of sickle cells under a cover slip is notoriously capricious, and Brandau<sup>4</sup> stated that in a given case, examination (wet smear) may be positive for the sickle cell trait at one time, at another negative. Some workers were able to demonstrate sickling in whole blood, and blood in various diluents<sup>8, 15, 19, 24, 27</sup> (1.25 per cent citrate in 1/8N sodium chloride, physiologic saline, serum from other patients), others were unable to reproduce these results.<sup>11</sup>

From Division of Laboratories, Newark Beth Israel Hospital, Newark, N. J.

In 1917, Hahn and Gillespie advocated the use of a small blood chamber in which carbon dioxide could be passed over a citrate suspension of blood.<sup>15</sup> In 1930, Scriver and Waugh suggested that a band be placed about the finger of an individual for five minutes before blood was drawn, the anoxic blood then demonstrating the trait more rapidly.<sup>20</sup> Hansen-Pruss,<sup>16</sup> in 1936, found that the addition of a drop of blood to a dried smear of one of several supravital stains (cresyl blue, janus green, or methylene blue) accelerated the rate of sickling. By this method, in 100 cases, 14 per cent were found to have the sickling trait, although the usually quoted figure is only half that amount.<sup>22</sup> In 1940, a comparison of the several methods of producing the trait (gas chamber, test tube, moist preparation, and the moist stasis preparation of Scriver and Waugh) revealed that the most reliable and the most practical method for the detection of the sickle cell trait is the moist stasis method of Scriver and Waugh.<sup>9</sup>

The differentiation between sickleemia and sickle cell anemia has been attempted frequently. In 1932, Diggs noted that sickle cells were seen more readily and in greater quantity in cases of sickle cell anemia than in instances of the sickling trait alone.<sup>7</sup> Sherman in 1940 proposed a method in which blood was collected anaerobically. In cases of sickle cell anemia, 30-60 per cent of the erythrocytes were sickled, while this was true in sickleemia to the extent of 1 per cent or less.<sup>17</sup>

A different approach to the laboratory diagnosis of this disease was made when the sedimentation rates were investigated. In 1927, Graham and McCarty noted that the erythrocyte sedimentation rate (E S R) seemed faster than normal,<sup>1</sup> a finding contradicted by later workers.<sup>4, 5</sup> In 1939, Bunting noted the fact that sickled erythrocytes from patients with sickle cell anemia did not form rouleaux, and in this condition did not sediment appreciably in one hour's time, whereas non-sickled forms from the same patients formed rouleaux and sedimented.<sup>8</sup> It was also noted that the uncorrected E S R may even be normal in the presence of marked anemia.<sup>2</sup> The characteristics of the E S R in sickle cell anemia were studied and it was noted that exposure to carbon dioxide caused sickling and a decrease in the E S R while oxygenation favored the development of rouleaux and accelerated the E S R. In 1944, Burch and Winsor investigated this property thoroughly and concluded that the variation in the E S R was a reversible procedure and could be controlled at will by exposing the blood either to carbon dioxide or oxygen.<sup>3</sup> From this and other data, a relationship between the differences in the E S R of blood saturated with carbon dioxide and oxygen was derived which was stated to be of diagnostic value in sickle cell anemia. In a study of 26 patients with sickle cell anemia and 60 patients who were normal or had diseases other than sickle cell anemia (371 determinations of which were done on the former and 239 on the controls), it was concluded that if the difference in the E S R's (called the diagnostic parameter or  $\Delta$ ) was 27 mm per hour or more, in 98 per cent of cases, sickle cell anemia would be present, and that the control subjects had 4 chances in much more than 10,000 of falling within the range for the sickle cell blood when the oxygen-carbon dioxide test is used.<sup>3, 9</sup> In the following year, the same workers reported their results when the diagnostic parameter had been in routine use on some services in Charity Hospital, New Orleans, for two years. In 61 consecutive

Negro admissions to one medical service, 44 per cent were found to have acute sickle cell anemia, a figure considerably higher than the usually quoted incidence. It was stated that in 437 control patients and 73 with sickle cell anemia, the diagnostic parameter did not give a false response in a single instance.<sup>30</sup>

Because of the reported accuracy and reliability of the test, and its simplicity and rapidity of performance, it was decided to test its application in a general hospital and to determine its practicability. It was hoped that during the evaluation of this test, previously unsuspected cases of sickle cell anemia would be discovered.

### METHOD

The blood specimens examined in this study were obtained predominantly from Negro outpatients attending the various clinics of the Newark Board of Health, Newark Beth Israel Hospital, and Newark City Hospital. In most cases the blood was obtained at the same time the routine serologic examination specimen was drawn.

The method described by Burch and Wiesor<sup>24-26</sup> was used with several minor modifications. Approximately 6-8 cc. of blood was drawn from a vein in the antecubital fossa and placed in a clean dry specimen bottle containing 15-25 mg. of sodium oxalate. The bottle was corked and rotated to insure thorough mixing. The relative proportion of blood to anticoagulant used does not seem to alter the E.S.R. appreciably.<sup>25-26</sup> Oxygen and carbon dioxide were introduced into separate 250 cc. Florence flasks and allowed to run in at the rate of 2-4 liters per minute for thirty to forty five seconds. A rubber stopper was then inserted into the mouth of the flasks. It was felt that the use of a Florence flask decreased the diffusion of the gas out of the container and that the larger size permitted a thinner layer of blood to be in contact with the gas over a larger surface area. About 2 cc. of blood was introduced into the flask by means of a graduated 5 cc. pipet and the flask rapidly sealed. This step usually took no longer than five seconds. The blood was allowed to remain in contact with the gas for about fifteen to twenty minutes during which the flask was rotated several times. The blood in the flask containing carbon dioxide turned a deep maroon in several minutes while that in the flask with oxygen assumed a bright scarlet color. No attempt was made to measure the degree of saturation by physicochemical means, the depth of color being sufficient indication. Before blood was placed in the Wintrobe sedimentation tubes the flasks were rotated so as to mix the blood thoroughly and render it homogeneous. The sedimentation tubes were tightly capped and suspended in a specially constructed rack. All readings were taken after one hour.

Concomitant sickle cell preparations were made. For the first 163 determinations, hanging drop preparations of oxalated whole blood in isotonic saline were used. Later it was felt that this method was not as accurate as the moist stasis method and accordingly moist stasis preparations<sup>32</sup> and wet sealed preparations of oxalated venous blood exposed to carbon dioxide were utilized. The latter, as previously described,<sup>32</sup> proved to be more accurate and was therefore adopted for the last 144 determinations.

All cases of sickling and high parameters were repeated whenever possible and all necessary clinical and laboratory data were obtained.

### RESULTS

Three hundred and seven determinations were performed upon 250 patients. Ten patients (4 per cent) had a diagnostic parameter of 27 mm. per hour or greater (table 1). One of these cases had acute sickle cell anemia, 7 had sickle cell anemia without anemia, and one case did not have sickle cell anemia. The remaining patient also demonstrated no sickle cell anemia, as evidenced by the relatively unreliable hanging drop method (it was not possible to recall this patient for a hemogram and a more accurate sickling preparation).

Fifteen patients (6 per cent) exhibited the sickling trait, and only one of these had acute sickle cell anemia. Of the 15, 8 patients had a diagnostic parameter

\* Hanging drop preparation

above 27 mm per hour and 7 were below that value (fig 1). The diagnosis of sickle cell anemia was satisfactorily excluded in 14 of the 15 patients by the absence of anemia, jaundice, attacks of abdominal pain or arthralgia, pretibial ulcers, or on the laboratory findings of normal erythrocyte counts, hemoglobins (Sahli method), and total white counts.

For the most part it was noted that repeated determinations upon the same individual were in close agreement. In case 15, the values for the differential sedimentation rates obtained on two successive days were equal (table 2). In cases 101, 106, 113, 114, and 121, numerous determinations showed a high degree of correlation (table 2). However, in cases 86 and 95, a variation in results appeared. In the former, the first five determinations were almost exactly similar. The sixth, performed a month later, exhibited a marked increase in the ESR of the blood exposed to the carbon dioxide. This was difficult to ascribe to the technic as the method was standardized and relatively simple to perform. The possibility that a qualitative difference existed in the blood at the later date can not be excluded. Case 95 was similar (table 2).

### DISCUSSION

A high diagnostic parameter was associated with the presence of sickle cell anemia in almost all cases. There might have been a perfect correlation if the blood of case 101 (table 1) had been examined by a more sensitive sickling test than the hanging drop method. The single case of sickle cell anemia examined in this study had a diagnostic parameter above 27 mm per hour. Only 50 per cent of the cases of sickle cell anemia without sickle cell anemia had a parameter of 27 mm per hour or more. One might conclude that the diagnostic parameter, while highly indicative of the presence of sickle cell anemia, does not offer a means of differential diagnosis between sickle cell anemia and sickle cell trait.

# CONCOMITANT INFECTIOUS MONONUCLEOSIS AND HEMOLYTIC ICTERUS

By DAVID H. APPELMAN, M.D., and MAURICE M. MORRISON, M.D.

THIS COMMUNICATION describes a case of hemolytic anemia occurring in the course of infectious mononucleosis. A careful review of the literature reveals no precisely similar case.

Dameshek<sup>1</sup> reported an instance of hemolytic anemia in a patient with infectious mononucleosis who had been given sulfadiazine. The patient had cold hemagglutinins in his serum. Our case differs from that of Dameshek in that sulfonamide preparations had not been given, there was no preceding infection, and tests of the serum for cold agglutinins were negative. Ellis, Wollenman and Stetson<sup>2</sup> described a case of acute hemolytic anemia in an illness resembling infectious mononucleosis. Their patient was unlike ours in that tests of the serum showed auto hemagglutinins and hemolysins together with a positive Donath-Landsteiner reaction.

## CASE REPORT

A 22 year old, white single male was admitted to the Beth El Hospital on September 30, 1946. He had been well until five weeks before his admission, when he noticed weakness, fatigability, sluggishness and rust-colored urine. Jaundice and fever appeared in the fourth week of illness. He was hospitalized following a fainting spell. As a child he had experienced attacks of weakness followed by fainting spells. He underwent an appendectomy in 1943. Repeated bouts of furunculosis were successfully treated with penicillin while he was in Germany in 1945. No history referable to malaria or other hospital diseases was elicited.

On his admission the patient was slightly asthenic, with icteric skin and sclerae. The pharynx was injected, and small discrete lymph nodes were scattered throughout the neck. The spleen was palpable 4 cm. below the costal margin. Rectal temperature was 103 F. No other significant findings were noted.

Laboratory examinations on the morning following his admission were: hemoglobin, 4.3 grams (18 per cent), red blood corpuscles  $\times 4$  million, and 8,800 leukocytes per cu. mm. The differential count showed 70 per cent lymphocytes, 28 per cent segmented neutrophils and 2 per cent staff neutrophils. A few atypical lymphocytes characteristic of infectious mononucleosis were seen. About 25 per cent of the red blood corpuscles were spherocytic. A marked anisocytosis was present. Reticulocytes numbered 7 per cent. Five normoblasts per 100 W.B.C. were found on the blood smear. Platelets numbered 390,000 per cu. mm. Bleeding time, coagulation time, clot retraction time and prothrombin time were normal. A sternal marrow aspiration revealed a granulocytic-erythrocytic ratio of 50:50. M. g. erythrocytes were normal in number and the granulocytic elements were made up of 35 per cent myelocytes, 35 per cent segmented neutrophils, 10 per cent metamyelocytes and 20 per cent staff neutrophils.

The heterophile agglutination test was positive to a dilution of 1:512. The red blood corpuscle fragility test<sup>3</sup> with hypotonic saline solutions showed initial hemolysis at 0.48 per cent and complete hemolysis at 0.42 per cent. (With normal blood, hemolysis usually begins in the tube containing 0.44 or 0.4 per cent salt solution and is complete in the tube containing 0.34 per cent salt solution.) The urine was strongly positive for urobilinogen. Bile hemosiderin and hemoglobin were absent from the urine.

Blood chemical examinations showed an icterus index of 15, a delayed van den Berg reaction and a serum protein of 7.1 grams per cent. The albumin was 3.9 Gm. per cent and the globulin was 3.2 Gm. per cent. Serum total cholesterol was 200 mg. per cent and the cholesterol esters were 125 mg. per cent. Urea nitrogen, sugar and chlorides were normal. The cephalo flocculation test was 3 plus.

From the Departments of Medicine and Hematology, The Beth El Hospital, Brooklyn, New York.

The Kline test was negative. Blood cultures showed no organisms. Repeated fecal examinations failed to reveal any parasites or ova. No malarial parasites were found in the bone marrow and peripheral blood specimens. The patient was Rh positive and group O. Agglutination tests for brucellosis, typhoid, paratyphoid A and B, and typhus fever were negative.

Röntgenologic examinations of long bones and chest were normal. The basal metabolic rate was plus 18. Fragility tests done on the blood of the patient's relatives were within normal limits and no cytologic abnormalities were found.

The patient was given 3500 cc. of blood during the first week of hospitalization. The hemoglobin rose to 5.5 Gm. (36 per cent) with a red blood cell count of 1.9 million. The other hematologic and biochemical examinations were relatively unchanged. The urinary urobilinogen reached a titer of 1:100.

Two weeks after admission additional laboratory examinations were done: tests for cold agglutinins for paroxysmal hemoglobinuria by Mackenzie's modification<sup>4</sup> of the Donath-Landsteiner test, and for Marchiafava's disease by the Ham and Horack<sup>5</sup> procedure were all uniformly negative. The heterophile agglutination test was positive in a dilution of 1:256. The Davidsohn exclusion test confirmed the diagnosis of infectious mononucleosis.

The clinical course during the ten weeks of hospitalization was uneventful. The temperature returned to normal on the twelfth day, after reaching a peak of 104 F. forty-eight hours after admission. The lymphadenopathy persisted. The spleen became barely palpable. A slight icteric tint to the skin was still perceptible on discharge.

Laboratory examinations carried out during the last week of hospitalization showed a hemoglobin of 9 grams (58 per cent) with a red blood cell count of 2.8 million. Leukocytes were 7000 per cu. mm. of which 52 per cent were segmented neutrophils, 4 per cent eosinophils, 42 per cent lymphocytes and 2 per cent monocytes. No atypical lymphocytes were seen. A few macrocytes and an occasional spherocyte were seen on the stained blood smear. Reticulocytes were 3 per cent and the platelets numbered 380,000 cu. mm. Sternal marrow showed a granulocytic-erythrocytic ratio of 60:40. Granulocytic series showed 20 per cent neutrophilic myelocytes, 10 per cent eosinophilic myelocytes, 12 per cent metamyelocytes, 15 per cent staff neutrophils and 5 per cent eosinophils. The icterus index was 17. Quantitative serum bilirubin was 0.8 mgs. per cent. The heterophile agglutination test was negative. The red blood cell fragility test had returned to normal. Initial hemolysis began at 0.44 per cent and was completed at 0.32 per cent. The urinary urobilinogen was positive in a dilution of 1:100.

There was nothing in the patient's history prior to the onset of the infectious mononucleosis to indicate a pre-existing hemolytic disease. The subject was not seen until eighteen months after discharge. He looked well, had no icterus, and the spleen was not palpable. Laboratory examinations at this time were: hemoglobin 15.4 grams (100 per cent) red blood corpuscles 4.6 million and 6,000 leukocytes per cu. mm. The differential count showed 51 per cent segmented neutrophils, 10 per cent staff neutrophils, 33 per cent lymphocytes, 5 per cent monocytes and 1 per cent eosinophils. No pathologic cells were seen. Reticulocytes numbered 1.5 per cent, platelets 450,000/cu. mm. Bleeding and coagulation time were normal. The heterophile agglutination test was negative. The red blood corpuscle fragility test with hypotonic salt solution showed initial hemolysis at 0.44 per cent and complete hemolysis at 0.34 per cent. Blood chemical examinations showed an icterus index of 4.3 units, a negative cephalin-cholesterol flocculation test and a zinc turbidity test of 6.2 units. Bile hemoglobin and hemosiderin were absent from the urine. The urinary urobilinogen was within normal limits.

#### COMMENT

Following the report of the laboratory findings, it became apparent that the patient had hemolytic anemia and infectious mononucleosis concomitantly. The diagnosis of infectious mononucleosis was supported by the lymphocytosis with atypical lymphoid cells, the positive heterophile agglutination test, the lymphadenopathy and the splenomegaly. However the unusual findings were the presence of jaundice, anemia, an increased red blood cell fragility to hypotonic salt solution, spherocytosis, increased urinary urobilinogen and an erythroblastic marrow, i.e., the findings characteristic of hemolytic anemia. The occurrence of infectious mono-

nucleosis with jaundice has been previously described<sup>8,9</sup> Infectious hepatitis might be considered as a possible diagnosis but cases of infectious hepatitis almost invariably show an increased resistance to hypotonic saline Paroxysmal nocturnal hemoglobinuria was ruled out by a negative Ham acid test Reed and Helwig<sup>10</sup> reported 300 cases of infectious mononucleosis of which 3 presented severe anemia, but the anemia was associated with a marked reduction of the white blood cells and platelets The authors considered this pancytopenia to be part of the infectious mononucleosis

### SUMMARY

Hemolytic anemia concomitant with infectious mononucleosis, was observed in a 22 year old white male whose history indicates no pre-existing hemolytic disease Recovery occurred spontaneously

# INFECTIOUS LYMPHADENOSIS (MONONUCLEOSIS) AND HEMOLYTIC ANEMIA IN A NEGRO, RECOVERY FOLLOWING SPLENECTOMY

By SLOAN J. WILSON, M D, CHARLES E. WARD, M D, AND LUTHER W. GRAY, M D

IN MOST instances, infectious lymphadenosis (mononucleosis) is not a diagnostic problem. In a recent publication, Dameshek and Grassi<sup>1</sup> state that the lack of reduction of red cells and platelets in infectious lymphadenosis (mononucleosis) is of considerable aid in distinguishing this disease from acute lymphatic leukemia, and that the association of well-defined anemia and/or thrombocytopenia with a marked degree of lymphocytosis in which abnormal lymphocytosis is conspicuous almost certainly indicates acute leukemia.

These authors reported a case of severe thrombocytopenic purpura in a patient who had infectious mononucleosis. Splenectomy resulted in an excellent platelet response. The case herein presented is another exception to these generally accepted concepts in the diagnosis of infectious mononucleosis. A young Negro male was found to have generalized lymphadenopathy, slight hepatomegaly, marked splenomegaly, an absolute lymphocytosis and a severe anemia. Although the clinical picture strongly suggested leukemia, the qualitative characteristics of the lymphocytes were those of infectious mononucleosis and this diagnosis was confirmed by a markedly positive heterophile agglutination test. In addition to the marked anemia there was also a reticulocytosis, moderately increased red cell fragility, an elevation in the icterus index, and an increased urinary excretion of urobilinogen. This was interpreted as a hemolytic anemia. The family history was entirely negative. Splenectomy was performed when the anemia became extremely severe and uncontrollable by transfusions, and a prompt recovery occurred.

Infectious lymphadenosis is rare in the Negro, but has been reported.<sup>2-5</sup> Anemia has been reported with this disease in but a few cases.<sup>6</sup>

This case is of interest not only because of its rarity, but also because of the possibility of hypersplenism with resultant hemolytic anemia, thrombocytopenia and moderate leukopenia. The hemolytic anemia was the predominating feature of the disease.

## REPORT OF CASE

H, a young adult colored male, aged 18 years, was admitted to the hospital May 28, 1944. He complained of headache, fever and chills. A diagnosis had been made on May 23, 1944, of influenza. Because of a marked anemia with an erythrocyte count of 2.46 and hemoglobin of 6 Gm., he was admitted to the medical service (C. E. W.) for further study. The family history was entirely negative for hemolytic anemia.

On examination, the patient appeared to be acutely ill. The sclerae were jaundiced. The lymph nodes of the neck, axillae and inguinal regions were enlarged. A systolic murmur was present in the apical region. The liver was palpable at the costal margin. The spleen was enlarged and extended 8 cm. below the costal margin and medially to the midline.

On May 31, 1944, he was seen by one of us (S. J. W.). The physical findings were the same as on admission. Blood studies at this time revealed the following: erythrocyte count 2.46 M. h. = 21.4 G. Hb. 6.0

The patient was studied at La Garde General Hospital, New Orleans, Louisiana.

Gm (51 per cent), leukocyte count 19 500, reticulocytes 9.5 per cent, icterus index 17 units heterophile agglutination test positive to a dilution of 1:896 urinary urobilinogen positive in a dilution of 1:50. A red cell fragility test showed initial hemolysis at 0.45 and complete at 0.32 (normal initial hemolysis 0.41 complete 0.30). No sickling of red cells was observed in a 24 hour wet preparation. The platelet level by the Rees Ecker method was 240 000 per cu. mm. The peripheral blood was studied by the supravital technic and after having been stained with Wright's stain. The following differential count was obtained, polymorphonuclear leukocytes 20 per cent, lymphocytes 77 per cent, monocytes 1 per cent, eosinophiles 2 per cent. The lymphocytes varied in size and staining reaction and were typical of infectious mononucleosis. The erythrocytes showed some polychromatophilia, anisocytosis, and slight stippling. Spherocytes were numerous.

FIG. 1. Graphic illustration of the hematologic response in a Negro with infectious mononucleosis and hemolytic anemia. Splenectomy resulted in recovery.

A sternal marrow biopsy on June 2, 1944 revealed marked hyperplasia. Extensive plaques of erythroid elements at the normoblastic level of cell maturation were observed. The other marrow elements were normal in appearance and maturation levels but were relatively decreased. Occasional young lymphocytes were observed.

The patient began to improve clinically and hematologically (see fig. 1). A second hemolytic crisis developed however with a drop of erythrocytes, leukocytes and platelets. Transfusions of 500 cc. each were given on June 10, 14 and 15. The erythrocyte count on June 15 was 1.23 M. with a hemoglobin of 4.25 Gm (27 per cent). Because of the uncontrollable hemolytic phenomenon a splenectomy was done (L.W.G.) on June 15, 1944. The spleen was greatly enlarged and removed with some difficulty. Two accessory spleens were also removed. The red cell count in the afternoon of the operative day was 2.550 000 and hemoglobin 8.5 Gm (55 per cent).

The spleen grossly was markedly enlarged and moderately firm. The weight was 860 Gm. The capsule was smooth and not thickened. The splenic pulp was red and scraped with ease. Microscopic examination revealed marked dilatation of the sinusoids which were filled with erythrocytes. The malpighian bodies were not enlarged and the germinal centers were not proliferative in type. This probably is explained on the basis that the infectious mononucleosis had subsided before the splenectomy, as the lymph nodes had also receded.

The postoperative course was uneventful. The patient was observed until October 26, 1944. No recurrence of the hemolytic phenomenon was observed. On this date the following laboratory data were obtained: erythrocytes 4,950,000, leukocyte count 12,800 (higher than the usual periodic observations), hemoglobin 15.3 Gm (98 per cent), platelets 415,000, differential, polymorphonuclear leukocytes 48 per cent, lymphocytes 47 per cent, monocytes 1 per cent, eosinophiles 4 per cent, urinary urobilinogen slightly positive in a 1:5 dilution, heterophile agglutination positive 1:20 dilution.

### DISCUSSION

As has been stated before, infectious lymphadenosis is rare in the Negro, but has been reported.<sup>2-5</sup> It was quite evident in our case that there was a considerable mixture of negroid and white stock. Although negroid characteristics were present, the hair was auburn and the skin a very light brown.

Infectious mononucleosis is a readily recognizable disease, running a characteristic course. One of its outstanding features is the lack of anemia. Read and Helwig<sup>6</sup> reported anemia in only 6 of 300 cases of infectious mononucleosis. In 3 of these patients, there was a rapid and simultaneous drop in red blood cells, white cells and platelets. This was followed by a gradual rise in all three of the formed elements of the blood.

The 3 cases of Read and Helwig and the case reported here again serve to emphasize that a diagnosis between lymphatic leukemia and infectious mononucleosis cannot always be made on the absence of anemia and the presence of immature lymphocytes. The cells must indeed be studied for qualitative differences and correlated with the heterophile agglutination test. Read and Helwig, in addition to mentioning a possible hemolytic phenomenon, believed that the anemia may be partially explained by infiltration of the bone marrow. It is interesting to note that in one of their cases (case 3) the icterus index was 3.1 at the time the red blood cells were 1,900,000 and the indirect Van den Bergh test 3.5 mg. No other data are given which would be of aid to determine whether or not a hemolytic process existed.

In the case presented in this report, the cause of the hemolytic process cannot be definitely stated. No familial history could be obtained. The spleen was considerably enlarged and microscopically typical of a marked hemolytic process, the sinusoids being distended with erythrocytes. It could well be that this represented another manifestation of hypersplenism. Doan and Wright,<sup>7</sup> Doan<sup>8</sup> and Dameshek and Estren<sup>9</sup> have discussed at length the various types of hypersplenism of the primary and secondary types. Specific primary diseases exist in which an unstable splenic reticulo-endothelial system either acutely or chronically destroys and/or inhibits the blood cells, platelets and granulocytes excessively. These are descriptively identified as congenital hemolytic anemia, essential thrombocytopenic purpura, primary splenic neutropenia and primary splenic panhematopenia. One or other of these primary syndromes may be simulated by any secondary involvement of splenic tissue. Doan and Wright,<sup>7</sup> Doan<sup>8</sup> and Dameshek and Estren<sup>9</sup>

mentioned many such diseases in their discussions of the subject Hemolytic anemia however, is not mentioned as occurring in infectious mononucleosis One can hypothesize that in this case the spleen was stimulated to overdestruction of red cells and a severe hemolytic anemia resulted, which necessitated its removal As Dameshek and Grassi<sup>1</sup> state The whole subject of spleen-bone marrow relationships under normal and pathologic conditions has only recently come to the forefront, and many questions related to the possibly increased activity of the spleen must await further investigation

### CONCLUSION

A case is presented of acquired hemolytic anemia and infectious lymphadenosis (mononucleosis) in a Negro Splenectomy for the uncontrollable hemolytic state was followed by prompt recovery

## ERYTHROCYTES AND ANEMIAS

EFFECTIVENESS OF VITAMIN B<sub>12</sub> IN COMBINED SYSTEM DISEASE. RAPID REGRESSION OF NEUROLOGICAL MANIFESTATIONS AND ABSENCE OF ALLERGIC REACTIONS IN A PATIENT SENSITIVE TO INJECTABLE LIVER EXTRACTS. *L. Berk, D. Denny Brown, M. Finland, and W. B. Castle*. From the Harvard Medical School and the Thorndike Memorial Laboratory of Boston City Hospital, Boston, Mass., New England J. Med. 239: 328-330, 1948.

The authors report observations on a patient with pernicious anemia who was sensitive to pork and beef liver extracts. While taking folic acid she developed severe neurologic manifestations of combined system disease. She was then treated with 5 micrograms of Vitamin B<sub>12</sub> for eight days without reaction. Reticulocytes began to rise on the fourth day and reached a peak on the sixth day. By the tenth day neurologic regression was evident and the changes are tabulated by the authors. Discontinuance of B<sub>12</sub> for seven days led to some relapse which again responded to further treatment.

This report indicates that B<sub>12</sub> in contrast to folic acid should prove effective against the neurologic as well as the hematologic manifestations of pernicious anemia and that B<sub>12</sub> is not responsible for sensitivity reactions to liver extract.

C A F

OBSERVATIONS ON THE EFFECTS OF FOLIC ACID ANTAGONISTS. FOLIC ACID, LIVER EXTRACT AND VITAMIN B<sub>12</sub> ON EMBRYONATED EGGS. A PRELIMINARY REPORT. *P. F. Wagley and H. R. Morgan*. From the Thorndike Memorial Laboratory, Boston City Hospital and the Department of Medicine, Harvard Medical School, Boston, Massachusetts. Bull. Johns Hopkins Hosp. 83: 275-278, 1948.

Injection of folic acid antagonists produced a diminution in the size and number of the blood islets of the yolk sac of the embryo and degenerative changes in the nuclei of the islet cells. Of the three antagonists used, 4-amino-pteroylglutamic acid produced the most marked histologic changes. Injection of folic acid prior to administration of the antagonist did prevent the changes in the hematopoietic tissue but the preliminary injection of B<sub>12</sub> did not have an effect in the amounts used.

R S E

THE BLOOD AND BONE MARROW IN THE SPRUE SYNDROME. A STUDY OF 63 CASES. *E. M. Irwin*. From the Department of Medicine, University of Edinburgh. Edinburgh M. J. 56: 28-29, 1948.

Hematologic studies are recorded on a group of 27 adults with nontropical sprue, 17 adults with tropical sprue and 19 children with celiac disease. In the majority of adults macrocytic anemias were present and in those patients not under liver treatment, a megaloblastic marrow. Patients with celiac disease showed microcytic hypochromic erythrocytes. These studies are related to the morphology of erythrocytes and are somewhat difficult to interpret, since many patients were on therapy.

C A F

THE ANEMIA OF INFECTION. VII. THE SIGNIFICANCE OF FREE ERYTHROCYTE PROTOPHYLLIN IN THE ANEMIA OF INFECTION WITH SOME OBSERVATIONS ON THE MEANING OF THE EASILY SPLIT-OFF IRON. *M. Grollman and J. A. Grollman*.

and M. M. Wintrub From the Department of Medicine School of Medicine, University of Utah Salt Lake City J Clin Investigation 27 245-259 1948

In pursuance of earlier studies demonstrating an increase in erythrocyte protoporphyrin and urine coproporphyrin associated with the anemia of infection, experiments were designed to establish the significance of free protoporphyrin in red cells (EP) also included in the present report are observations relative to the nonhemoglobin iron, or easily split-off iron (ESFe) of the erythrocytes. Data obtained in the course of reticulocytosis produced in animals by hemolytic agents (employing phenylhydrazine and immune erythrocyte antibodies) and by restoration of deficiency anemias (pyridoxine deficiency in pigs and pernicious anemia in a human subject) and studies of effluent blood from congested spleens in nembutal treated animals indicated that the EP is greater and the ESFe less in immature than in mature red cells and that the erythrocyte EP in splenic venous blood was increased following splenic stasis.

These findings are interpreted as indicating that (a) an increase in EP usually signifies incomplete hemoglobin synthesis, as in reticulocytes in red cells altered by iron deficiency and those damaged by toxins or other factors or it may represent evidence of hemoglobin degradation, (b) the ESFe appears to be a degradation product of hemoglobin associated with the maturation destruction and perhaps senescence of red cells.

C.P.E.

#### VOLUME CHANGES IN HEMOLYTIC SYSTEMS CONTAINING RESORCINOL, TAUROCHOLATE AND SAPONIN E

Ponder From Nassau Hospital Mineola Long Island N Y J Gen Physiol 31 325-335 1948

Hemolysis produced by some lysins is preceded by a loss of potassium from the human red cell, and in the case of other lysins it may also be preceded by an increase in cell volume. A modification of the Hamburger (or van Allen) hematocrit method permitted the measurement of intact cells and the percentage of complete hemolysis. The results indicate that volume increases may be quite small while the potassium losses are larger, and that the volume changes may be unequal for equal potassium losses produced by different lysins.

O.P.J.

#### THE PERMEABILITY OF HUMAN RED CELLS TO CATIONS AFTER TREATMENT WITH RESORCINOL, N-BUTYL ALCOHOL, AND SIMILAR LYSINS E Ponder From Nassau Hospital Mineola Long Island N Y J Gen Physiol 32 53-62, 1948

In systems of washed cells of freshly drawn heparinized human blood to which various concentrations of resorcinol have been added, the loss of potassium increased with time. When potassium is made to re-enter cells which have previously lost it the quantity of sodium which leaves the cell is approximately the same as the quantity of potassium which enters.

O.P.J.

#### HYPOPHYSE ET HEMATOPOIESE I LE RETENTISSEMENT DE L'HYPOPHYSECTOMIE SUR L'HEMATOPOIESE DU RAT ALBINO (HYPOPHYSECTOMY AND HEMATOPOIESIS I THE EFFECT OF HYPOPHYSECTOMY ON HEMATOPOIESIS IN THE WHITE RAT L. Argy M. Gabe and F. Stumitsky Rev Hemat 3 154-179 1948

Twenty four male albino rats were hypophysectomized the weight and blood cell counts were followed and the bone marrow was examined. Histologic examinations using several techniques were utilized among them silver impregnation of the reticulum and detection of iron.

Some of the results are mere confirmation of what was already known namely anemia scarcity of erythroblasts in the marrow smears and splenic atrophy with increase of the lymphoid follicles.

Some points are of interest the effect on the bone marrow concerns not only the red cell series but also the myeloid series.

The osmotic fragility of the red cells in saline solution is decreased in the hypophysectomized rats. The increase in the lymphoid follicles in the spleen is nothing but a reflection of a general hyperplasia of the lymphoid tissues (lymph nodes Peyer's patches).

The study, using iron staining shows a striking hemosiderosis in the hypophysectomized animals. The authors believe that the bone marrow hyperplasia is linked to the thyroid atrophy which follows the hypophysectomy.

J.P.S.

**SULFHYDRYL COMPOUNDS AND THE SICKLING PHENOMENON** A PRELIMINARY REPORT *L Thomas and C A Stetson Jr* From the Department of Pediatrics, Johns Hopkins University Medical School and the Harriet Lane Home for Invalid Children Johns Hopkins Hospital Baltimore Maryland Bull Johns Hopkins Hosp, 83 176-180, 1948

The use of several reducing substances to produce rapid reduction in oxygen tension so as to promote sickling of susceptible cells is the subject of this preliminary report. Of the substances used, a saturated solution of hydrogen sulfide was the most active in producing sickling. Solutions of BAL and cysteine were also effective. After exposure to these substances the sickling phenomenon was found to be still reversible when the suspension was exposed to air. The concentrations of each substance necessary to produce sickling were also sufficient to produce a positive nitroprusside reaction.

R S E

**RAPID STAINING OF HEINZ BODIES IN SMEARS** *S H Webster E J Leljegren and D J Zimmer* From Laboratory of Physical Biology National Institute of Health Bethesda Maryland Stain Technol 23 97-98, 1948

The authors have used with equal success either a 0.2 per cent solution of methyl violet or crystal violet in 95 per cent ethyl alcohol. Freshly prepared air-dried moderately thick blood smears are covered with this solution for one half minute. The surplus dye is removed in running tap water.

O P J

**THE CYTOPLASMIC BASOPHILIA OF MARROW CELLS. THE DISTRIBUTION OF NUCLEIC ACIDS** *J N Davidson I Leslie and J C White* From the Department of Biochemistry St Thomas's Hospital Medical School London, England J Path & Bact 60 1-20, 1948

It has been shown by the application of Brachet's ribonuclease test and Caspersson's ultra violet absorption technic that young blood cells contain ribonucleic acid which diminishes progressively as the cells mature. The present study is an attempt to place some of these impressions on a quantitative basis. Marrow samples from 15 normal individuals and 22 suffering from various blood dyscrasias were prepared for studies of films, sections and chemical analysis. Quantitative determinations were made for total nucleic acid phosphorus, ribonucleic acid phosphorus and deoxyribonucleic acid phosphorus. The mean values of these for normal human marrow were 20.7, 14.2 and 6.9 mg of P per 100 Gm of fresh tissue respectively. These values were increased in hyperplastic immature marrows. Nucleic acid levels decreased during reticulocytosis in pernicious anemia following specific therapy and eventually returned to normal. If a hyperplastic marrow contains many cells of medium maturity, then the deoxyribonucleic acid phosphorus value is elevated. The high ribonucleic acid content of the cytoplasm and nucleoli of the younger marrow cells is apparently connected with the ability to pass through a series of mitotic divisions and to elaborate hemoglobin and specific granules. The nucleolus associated chromatin which increases as the nucleolar ribonucleic acid diminishes appears to persist after the cell has lost its power to divide.

**INTRODUCTION BIOLOGIQUE À L'ÉTUDE DES ANALOGUES DE L'YPERITE (SUBSTANCES DITES MOUTARDES À L'AZOTE OU AU SOUFRE) ÉTUDE CRITIQUE DES RÉSULTATS CLINIQUES OBTENUS LORS DU TRAITEMENT DE 40 HÉMATOPATHIES MALIGNES PAR UNE MOUTARDE À L'AZOTE. PREMIERS RÉSULTATS DE RECHERCHES BIOLOGIQUES EFFECTUÉES AU COURS DE L'ÉTUDE THÉRAPEUTIQUE DES ANALOGUES DE L'YPERITE (BIOLOGIC INTRODUCTION TO THE STUDY OF ANALOGUES OF TOXIC GASES [SUBSTANCES CALLED NITROGEN MUSTARD OR SULFUR MUSTARD] CRITICAL STUDY OF THE CLINICAL RESULTS OBTAINED DURING TREATMENT BY NITROGEN MUSTARD OF 40 MALIGNANT BLOOD DISEASES. FIRST BIOLOGIC RESEARCH RESULTS OBTAINED DURING THE THERAPEUTIC STUDY OF THE ANALOGUES OF TOXIC GASES)** *L Jastrow Besançon S Lamotte Barrillon and Cl Polonovski* Sem Hopit Paris 24 1511-1531, 1948

A complete historical and bibliographical review on mustard gas is given. The results of the authors' observations in 40 cases of malignant blood diseases, 19 cases of Hodgkins disease with nitrogen mustard are presented. The following conclusions were reached: Nitrogen mustard is often badly tolerated and

therefore it should be reserved for cases which can not be treated by x rays for practical reasons, and above all, for cases which become refractory to x rays. The very widespread forms are also more easily treated by nitrogen mustard but the results are usually of short duration. The importance of following hematologic changes is emphasized. Nitrogen mustard should not be given sooner than two months after radiotherapy. The results in the terminal cases of Hodgkins disease were disappointing.

The third part of this work is an experimental study of the methyl bis  $\beta$ -chloroethylamine in regard to the skin sensitivity, glucose and protein metabolisms, and antibody formation. In vitro the bactericidal activity of the drug was tested on several micro-organisms. The effect in vitro on the osmotic fragility of red cells on coagulation mechanism, and on different enzymes was also considered. Some derivatives, the ethyl instead of methyl and the brom instead of chloride, were tried in different diseases with good results. Finally, the prophylactic effect of hexamethylen tetramine against the toxic manifestations of the drug appears effective in rabbits and mice, and confirms the previous in vitro studies.

J.P.S.

**THE NATURE OF ANAEMIA IN LEUKAEMIA** D. H. Collins and W. McL. Ross. From Department of Pathology and Bacteriology, University of Leeds, England. *J. Path. & Bact.* 60: 63-74, 1948.

Fifty consecutive cases of leukemia were studied from 1943 to 1947. A significant anemia was present in every case of acute leukemia, in 75 per cent of the cases of chronic lymphatic and 65 per cent of the chronic myelogenous leukemias. The anemia of chronic lymphatic leukemia tended to be more severe at the time of diagnosis and later toward the end. Nucleated red cells appeared in the blood commonly in chronic myelogenous and acute leukemias. The author emphasized that, in the absence of icterus or osseous metastases, erythroblastosis in an adult with only moderate anemia should bring myelogenous leukemia to mind. In both lymphatic and myelogenous leukemia blood loss and destruction may aggravate the anemia. But in addition lymphatic leukemia has a hypoplasia of erythropoietic tissue through a crowding of the marrow by lymphocytes and myelogenous leukemia has a defective or disorderly erythropoiesis from a hyperplastic marrow. Some evidence has been presented to indicate that either pernicious anemia or a severe megaloblastic macrocytic anemia may precede the onset of acute leukemia.

O.P.J.

## BLOOD PIGMENTS

**METHEMALBUMIN. I. APPEARANCE DURING ADMINISTRATION OF PAMAQUINE AND QUININE** M. Reissfeld, C. G. Zubrod, W. D. Blake, and J. A. Shannon. From the Department of Medicine, New York University College of Medicine, and the Research Service, Third (New York University) Medical Division, Goldwater Memorial Hospital, New York City, and the Department of Pharmacology and Experimental Therapeutics, The Johns Hopkins University, Baltimore, Maryland. *J. Clin. Investigation* 27: 138-143, 1948.

Methemalbumin consistently appeared in the serum of individuals receiving antimalarial therapy with both quinine and pamaquine but did not complicate treatment with either drug when supplied alone or develop in patients receiving pamaquine and quinacrine concurrently.

A new and convenient procedure is described for the photometric determination of methemalbumin concentrations in serum utilizing an absorption band at 405 m $\mu$ . This method is applicable in the absence of hemoglobinemia and entails only the determination of the serum bilirubin concentration to obtain a factor for correction of the serum blank.

C.P.E.

**METHEMOGLOBINEMIA AND SULFHEMOGLOBINEMIA** C. A. Finch. From the Medical Clinics of Harvard Medical School and the Peter Bent Brigham Hospital, Boston, Massachusetts. *New England J. Med.* 239: 470-478, 1948.

The normal red cell mechanism for reducing methemoglobin and the ways in which this can be influenced are discussed. Methods of identifying methemoglobin and sulfhemoglobin clinical pictures associated with these pigments, etiologic agents in their production, and treatment are reviewed.

C.A.F.

activity in the hemophilic like blood and in combinations of the latter with normal blood demonstrated only a slight consumption of prothrombin in the course of the clotting process. It is concluded that the effect of this inhibitory agent was to impede the conversion of thromboplastinogen to thromboplastin. An explanation is thus afforded for the failure of certain patients with hemophilia and hemophilic like disorders to respond satisfactorily to transfusion therapy or the administration of antihemophilic globulin.

C P E

RELATION OF COMPLEMENT TO BLOOD COAGULATION *F D Mann and M Hurn* From the Division of Clinical Laboratories Mayo Clinic Rochester Minnesota *Proc Soc Exptl Biol & Med* 67 83-85, 1948

The role played by complement in the conversion of prothrombin to thrombin was studied by means of one and two-stage assays of thrombin production after recalcification and addition of thromboplastin in plasma freed of complement activity by aging by treatment with zymine and with ammonia. It was concluded that inactivation of complement by these methods prevents thrombin formation without significantly impairing the activity of prothrombin.

C P E

THE EFFECT OF HEPARIN AND DICUMAROL ANTICOAGULANT THERAPY UPON THE ERYTHROCYTE SEDIMENTATION RATE *S W Coggriff* From the Department of Medicine College of Physicians and Surgeons Columbia University and the Presbyterian Hospital New York City *J Clin Investigation* 27 435-438, 1948

The influence of anticoagulant therapy on the suspension stability of red cells was studied in 10 subjects receiving heparin 10 receiving dicumarol and in 5 recipients of both drugs concurrently. It was determined that in therapeutic dosages heparin and dicumarol do not significantly alter the erythrocyte sedimentation rate and that the results of this test are therefore not invalidated by interference from the effects of these drugs.

C P E.

## BLOOD PRESERVATION AND FRACTIONATION

BLOOD AND ITS DERIVATIVES *S T Gibson* From the Medical Clinic of the Peter Bent Brigham Hospital and the Department of Medicine Harvard Medical School, Boston, Massachusetts *New England J Med* 239 544-556 and 579-589 1948

This article with its bibliography of 381 references serves as an excellent review of the large amount of work undertaken during the war years on blood preservation and the uses of its various products.

Some of the general topics dealt with are blood preservation, reactions to blood products (especially serum hepatitis), procurement and fractionation of plasma therapeutic uses of albumin and other plasma components.

## BOOK REVIEWS

---

*Pathology of Nutritional Disease* By RICHARD H FOLLIS JR Springfield Ill C C Thomas 1948 pp 76

This is a beautifully printed and illustrated work in which the pathologic disturbances associated with nutritional deficiencies are described. The book is divided into six sections dealing with deficiencies of the essential elements: the essential amino acids, the fat and water soluble vitamins, and the pathologic anatomy of specific tissues. It contains superb illustrations both of gross and histologic material. There are

Twenty new born infants were found to have a high capillary resistance, about 50 centimeters of mercury. Among 16 premature infants, only 5 had a similar increased resistance, while 11 had a lower resistance, and 2 of the latter group (twins of 950 and 900 grams birth weight) had only 5 and 10 centimeters of mercury. The esculoside given to the mother during the labor seemed not to be effective on the capillary resistance of the child.

In conclusion, the authors believe that estrogen plays a great part in the capillary fragility of pregnancy and believe that the administration of folliculin to premature infants is not without danger.

J.P.S.

THREE-STAGE ANALYSIS OF BLOOD COAGULATION J. H. Milstone From Department of Pathology, Yale University School of Medicine New Haven Conn. *J. Gen. Physiol.* 31: 301-324, 1948.

The blood-clotting mechanism has been analyzed by a procedure which devotes a separate experimental step to each of the three primary reactions. The activation of prothrombin by thrombokinase followed the course of a bimolecular reaction. The activation of prothrombokinase involved an autocatalytic reaction.

O.P.J.

ACCELERATOR GLOBULIN AND ANTITHROMPHILIC GLOBULIN IN THROMBIN FORMATION FROM Aprotrombin AND IN HEMOPHILIC BLOOD J. H. Ferguson and J. H. Lewis From the Department of Physiology University of North Carolina, Chapel Hill North Carolina. *Proc. Soc. Exper. Biol. & Med.* 67: 228-231, 1948.

A series of *in vitro* experiments are reported designed to characterize more completely an accessory clot promoting factor variously designated as labile factor (Quick), factor V (Owren) and accelerator globulin (Ware, Guest and Seegers). This factor, present in fresh plasma apparently potentiates by some mechanism unrelated to the plasma protease system, the conversion of prothrombin to thrombin in the presence of active thromboplastin and the calcium ion. Tests conducted with a purified fraction of bovine plasma containing the factor demonstrated a loss of potency with aging; its deterioration under these conditions occurring independently of prothrombin inactivation. Applied in the fresh state however or after storage in the frozen state, this factor effectively restored the original activity of aged prothrombin preparations.

The factor is possessed of no antihemophilic properties, its action being unrelated to that of thromboplastin or any of its precursors or activators. A naturally occurring deficiency of this plasma factor is believed to be the basis of a specific bleeding disorder, Owren's disease, (*Lancet* 232: 446, 1947) to be distinguished from hemophilia, idiopathic hypotherbinemia and other hemorrhagic syndromes.

C.P.E.

ACTIVATION OF PLASMA THROMBOPLASTINOGEN AND EVIDENCE OF AN INHIBITOR A. J. Quick and M. Stefani From the Department of Biochemistry, School of Medicine Marquette University, Milwaukee Wisconsin. *Proc. Soc. Exper. Biol. & Med.* 67: 111-112, 1948.

The first reaction involved in the mechanism of blood clotting according to the authors is the enzymic conversion of the thromboplastic precursor thromboplastinogen, a normal plasma constituent, to active thromboplastin through the agency of a platelet factor. In hemophilia the clotting defect is related primarily to a deficiency of thromboplastinogen, the platelets in this disorder exhibiting normal clot promoting activity when added to deplateletized normal plasma. Evidence is cited (J. Clin. Investigation 25: 814, 1946 and *Science* 106: 473, 1947) indicating that the situation in hemophilia is occasionally complicated by the appearance of an inhibitory factor in the blood which imparts to the latter anticoagulant properties.

A case is described in which a hemophilia like disorder developed following pemphigus. The prothrombin activity assayed with serial dilutions of thromboplastin was normal; thus excluding the presence of an antithromboplastin. The clotting time of this patient's blood was markedly prolonged; moreover it was essentially unaltered by the addition of normal blood, hence, the abnormality was presumably not attributable to a deficiency either of thromboplastinogen (as in true hemophilia) or of the platelet factor. Since the clotting time of normal blood was delayed when mixed with the patient's blood it is assumed that a clot inhibitor was operative. Finally, since measurements of prothrombin

activity in the hemophilic like blood, and in combinations of the latter with normal blood demonstrated only a slight consumption of prothrombin in the course of the clotting process, it is concluded that the effect of this inhibitory agent was to impede the conversion of thromboplastinogen to thromboplastin. An explanation is thus afforded for the failure of certain patients with hemophilia and hemophilic like disorders to respond satisfactorily to transfusion therapy or the administration of antihemophilic globulin

C.P.E.

RELATION OF COMPLEMENT TO BLOOD COAGULATION *F. D. Martin and M. Hahn* From the Division of Clinical Laboratories, Mayo Clinic Rochester Minnesota. *Proc. Soc. Exptl. Biol. & Med.* 67: 83-85, 1948

The role played by complement in the conversion of prothrombin to thrombin was studied by means of one and two-stage assays of thrombin production after recalcification and addition of thromboplastin in plasma freed of complement activity by aging by treatment with zymine and with ammonia. It was concluded that inactivation of complement by these methods prevents thrombin formation without significantly impairing the activity of prothrombin

## BOOK REVIEWS

---

*The Pathology of Nutritional Disease*. By RICHARD H. FOLLIS, JR. Springfield, Ill.: C. C. Thomas, 1947. Pp. 276.

This is a beautifully printed and illustrated work in which the pathologic disturbances associated with various nutritional deficiencies are described. The book is divided into six sections dealing with deficiencies in general, the essential elements, the essential amino acids, the fat and water soluble vitamins, the essential fatty acids, and the pathologic anatomy of specific tissues.

There are 791 references and 71 superb illustrations, both of gross and histologic material. There has

been need for such a carefully conceived work and the book is recommended highly to nutritionists, internists, and pathologists

WILLIAM DAMESHEK

*El Diagnóstico por la Punción Ganglionar* 1947 By G. FORTEZA BOVER. Valencia: Editorial Saber, 1948. In Spanish, 146 pages, 55 figures in black and white.

In referring to the history of lymph node puncture, the author points out that although it had been recommended as a means of diagnosis in isolated cases since the beginning of the century, it had come into general use only following the publications of Ellis and Martin (1930-1934) in the United States and of A. Pavlovsky of Buenos Aires (1933-34). Thereafter, well documented monographs by Lutrozu, Weill, Stabel, Tischendorf, Leitman and others appeared.

Utilizing the technique recommended by Pavlovsky, Forteza Bover presents his experience, beginning by describing in detail the cytomorphology of normal and hyperplastic lymphatic tissue. The disorders of lymphoid tissue are then described, beginning with the simple hyperplastic processes. There are excellent illustrative photomicrographs and colored plates.

In tuberculous adenitis, four stages are described: (1) initial tuberculous hyperplasia, (2) granulomatous transformation with necrosis and the presence of Langhans' giant cells with necrosis, (3) caseous necrosis and (4) purulent effusion. Careful descriptions of Boeck's sarcoid are given with figures illustrating the difficulties in differential diagnosis from tuberculous adenitis.

The author's studies of Hodgkin's disease are in agreement with those obtained by previous workers who have utilized similar diagnostic techniques. In lymphosarcoma, the cytologic characters of tumor formation are well depicted. However, in the diagnosis of follicular lymphoblastoma, the author considers the cytologic picture as being nonspecific and requiring an open biopsy for a definite diagnosis.

The pictures obtained in metastatic malignancy are of great value and Stabel's descriptions of the cellular elements which permit diagnosis are followed.

This book is well presented with good documentation and some excellent color plates. There are some original observations in Boeck's sarcoid and comprehensive and detailed studies of Hodgkin's disease. The book is recommended particularly to those who wish to become acquainted with the technique of and results obtained from lymph node puncture and study of the adenogram.

ALFREDO PAVLOVSKY

*New Staining Methods in Hematology* 1948 By J. GARCIA BLANCO AND G. FORTEZA BOVER. Valencia: Editorial Saber, 1948. In Spanish, 93 pages, 19 plates in color and 11 engravings in black.

The authors describe staining methods which were at first used histochemically but which were later applied to studies of the blood and bone marrow.

The various oxidase methods are described. The use of tetrabromophenolphthalein for staining hematopoietic tissues is described for the first time, used both singly and in combination with the peroxidase methods.

In the method which the authors call T.F.S. (Neosina), they utilize tetrabromophenolphthalein to retain the cellular structure of the various tissues. T.F.S. appears to react with the simple proteins and the prosthetic groups of the cellular structures, causing color combinations which depend upon the isoelectric point of the substrate. They also use the combined method with eosin and methylene blue with which beautiful contrast pictures are obtained.

This book is carefully and clearly written with exact descriptions of the techniques used and is exceptionally well illustrated. The excessive detail in the described techniques is somewhat confusing in the minutiae. For this reason, it is unfortunate that the authors did not complete their work by presenting a precise critique of the different staining techniques, thus advising which of the methods used is of greatest application in a given instance.

MARCH, 1949

### URETHANE (ETHYL CARBAMATE) THERAPY IN MULTIPLE MYELOMA

By J PHILIP LOGE, M D , AND R WAYNE RUNDLES, M D

INTEREST in the growth-suppressive properties of the carbamic esters, known for many years from general biologic studies, was renewed in 1945 by the investigations of Templeman and Sexton.<sup>1</sup> In studying the effect of ethyl phenylcarbamate on the growth of plant seedlings, they confirmed the earlier work of Lefèvre showing that this chemical retarded or even arrested plant growth, with various structures undergoing bulbous hypertrophy. Cytologically it appeared that mitosis was blocked in pseudometaphase, leading to the irregular formation of monstrous nuclei. Haddow and Sexton<sup>2</sup> then studied the effect of different carbamic esters on experimental animal tumors. They found that the common urethane, ethyl carbamate, was the most promising compound. It produced a transient increase in mitosis in normal tissues, and a significant retardation in the growth of spontaneous mammary cancer in the mouse and in the growth of the Walker rat carcinoma 256. The histologic structure of the tumors was profoundly altered.

Clinical trials using urethane and isopropyl phenylcarbamate in the treatment of advanced inoperable cancer were then undertaken. Amelioration was observed in a few cases but the results were generally disappointing. It was noted, however, that a fall in the leukocyte count occurred with some regularity. The experiments were then modified to include myeloid and lymphatic leukemia. Here the effects were vastly more pronounced, indeed comparable in many ways to those obtained by roentgen irradiation.<sup>3</sup> Following the report of Paterson, Ap-Thomas, Haddow, and Watkinson,<sup>3</sup> urethane began to be used extensively in the treatment of leukemias and widespread tumors in clinics throughout the world.<sup>4-11</sup>

The therapeutic limitations of urethane have become clearer as experience has widened. In disseminated cancer, in spite of an occasional success, there is usually no benefit from this therapy.<sup>5-9</sup> In localized lymphomas, roentgen irradiation remains the treatment of choice.<sup>14</sup> In acute leukemias, there is generally no improvement.<sup>4</sup> In chronic leukemias the net clinical benefit in many cases is probably less than that obtainable by standard methods of treatment. A disease in which exceptional therapeutic results may occur, however, is multiple myeloma, for changes have been observed following urethane administration which appear to be unique in the therapy of this disease.

From the Department of Medicine, Duke University School of Medicine and The Hematology Laboratory, Duke Hospital, Durham, North Carolina.

This study was aided by a grant from the Anna H. Hanes Fund.

The major features of multiple myeloma have been reviewed recently by Bayrd and Heck<sup>16</sup> and Lichtenstein and Jaffe.<sup>18</sup> It is a uniformly malignant disease progressing to a fatal termination in an interval varying from a few weeks to some times several years. The disease results essentially from the excessive proliferation of abnormal plasma or myeloma cells within the bone marrow. Anemia, leukopenia and at times thrombocytopenia result. Skeletal support becomes seriously impaired as the bones soften due to diffuse demineralization or to the formation of multiple areas of osseous destruction showing virtually no detectable attempt at repair. A complex abnormality of the body proteins is a feature of the disease being manifested by abnormally high serum protein values, hyperglobulinemia and often Bence-Jones proteinuria. Grave renal disease is a commonly associated finding.

Many different types of therapy have failed to alter significantly the clinical course of multiple myeloma. Roentgen irradiation, which has been used extensively, is fairly effective in relieving localized bone pain.<sup>17, 18</sup> Radioactive phosphorus, likewise, may relieve skeletal pain but even with doses large enough to produce leukopenia and thrombocytopenia there has been no overall improvement.<sup>19</sup> A few patients with multiple myeloma have been treated with nitrogen mustard compounds but the results have been disappointing.<sup>20-22</sup> Myeloma cells do not decrease in number in the bone marrow and there is no change in the histologic structure as observed in serial biopsies.<sup>23</sup>

Another approach to the chemotherapy of multiple myeloma was introduced by Snapper<sup>24, 25</sup> who used injections of stilbamidine and pentamidine combined with a diet low in animal protein. Symptomatic improvement and even bony recalcification was noticed in some patients. Myeloma cells persisted in the bone marrow without quantitative decrease, however, as did Bence-Jones proteinuria and hyperglobulinemia. Relapses occurred. Serious toxic reactions limited the usefulness of the diamidine compounds. Antimony compounds were used by Rubinstein<sup>26</sup> with similar results.

Reports of urethane therapy in patients with multiple myeloma are few. Paterson and her co-workers<sup>3</sup> observed no improvement after giving urethane to 2 patients with multiple myelomatosis. Berman and Axelrod<sup>9</sup> gave 72 Gm. of urethane to a 51 year old man with multiple myeloma but discontinued therapy when leukopenia developed. Hyperglobulinemia and Bence-Jones proteinuria was unchanged. Serial x-rays showed no change. Alwall<sup>27</sup> used urethane in the treatment of two patients with multiple myeloma. To one who complained mainly of skeletal pain he gave 3-4 grams of urethane daily for three months, without noticeable improvement. Stilbamidine was then injected intravenously and he was rather promptly relieved of pain. Other aspects of the disease were not affected. A second patient whose complaints related to anemia was given urethane alone and observed over a period of eight months. The anemia, albuminuria, hyperglobulinemia, and rapid sedimentation rate all improved considerably during the first four months of treatment and myeloma cells could no longer be found in the bone marrow.

This spectacular but isolated result suggested to us a more extensive and pro-

longed trial of urethane therapy in multiple myeloma. We have now studied the early therapeutic responses of 4 patients to urethane during observation and follow-up periods ranging from seven to thirteen months. Other types of specific therapy have been withheld. The detailed case histories follow.

## CASE REPORTS

**Case 1 C F H, Unit No B-25150.** This 41-year-old colored woman was referred to Duke Hospital on January 28, 1948. Her health had been good until six months earlier when she began to have chest pain when coughing or when pressure was exerted against her ribs. In the course of another two or three months she was forced to quit work because of pain along the spine and about her hips. The skeletal pain increased progressively. During her last month at home she was unable to walk or even get out of bed. She lost about ten pounds in weight.

Physical examination showed her to be a well-developed, well-nourished colored woman unable to move about on the examining table without acute discomfort. Pressure over the sternum, ribs, and spines of the vertebrae was exquisitely painful. The remainder of the examination disclosed no relevant abnormalities.

Examination of the peripheral blood showed that there was a severe anemia with immature erythrocytes, plasma cells, and nucleated red cells in the circulating blood (table 1). Rouleaux formation was

conspicuous in the blood films. Urinalysis showed a small amount of protein and a trace of Bence Jones protein. The excretion of phenolsulphonphthalein dye was not impaired. Serologic tests for syphilis were negative. The serum proteins were 13.2 Gm. per 100 cc. with 4 Gm. of albumin and 9.2 Gm. of globulin on one determination and 10 Gm. with 3.4 Gm. albumin and 6.6 Gm. globulin on another (table 5). The blood calcium was 12.4 Gm. per 100 cc., phosphorus 3.6 Gm., and alkaline phosphatase 3.1 Bodansky units per 100 cc. A bromsulphalein test of liver function, using 5 mg. of dye per kilogram of body weight showed 7 per cent retention after 45 minutes. Roentgen examination of the skeleton (fig. 1 A and B) showed pronounced generalized demineralization with small and large areas of non-reactive destruction in the skull, ribs, vertebrae, pelvis and long bones. There was partial collapse of the ninth and twelfth thoracic vertebrae.

Bone marrow was obtained by sternal aspiration. The bone was so soft that there was almost no resistance to insertion of the needle. In the stained films the marrow was exceedingly cellular. In most areas there were virtually no cells other than abnormal plasma cells (fig. 1, C). These varied from the size of the ordinary plasma cells to some two or three times as large. Many had double or triple nuclei. The latter contained one, two, or even three prominent nucleoli, some as large as one half the diameter of the nucleus.

The patient was admitted to the hospital on 2/18/48 for a trial of urethane therapy. The drug was tolerated well in divided doses by mouth and between 2/21/48 and 3/9/48, 85 Gm. were given. A leukocytosis of 19,000 developed on the fourth day of therapy. The white blood count then gradually fell to 2,900 on the sixteenth day. Urethane was withheld for seventeen days after which it was resumed in a dose of 15 to 2 Gm. per day until another 35 Gm. had been administered. During the first two weeks in the hospital her temperature ranged from 37 C. to 38.3 C. with one rise to 39.6 C. Afterwards her temperature was normal. Bone pain gradually became less until she was entirely comfortable while resting in bed. After one month in the hospital she was able to return home. There she gradually extended her activity until she could sit at the table with her family for meals and walk by holding to furniture. Pain of sciatic radiation developed after a period of over exertion but this subsided when her activity was again restricted. Three and one-half months after the beginning of therapy she was able to walk unaided and without difficulty.

The peripheral blood values (table 1) showed progressive improvement following the administration of urethane. Immature granulocytes, plasma cells and ocellated red cells disappeared in a few weeks from the circulating blood. After two months of therapy the bone marrow was re-examined. An exceedingly cellular marrow was again obtained but the predominant cells were now normal erythroid and myeloid elements (table 1). Scattered through the films there was an occasional small cluster of plasma cells greatly altered in morphology (fig. 1 E). Their cytoplasm was now irregular in contour, stained a denser blue and often contained light areas suggestive of early vacuolization. Their nuclei were extremely eccentric and pyknotic. Basophilic granules in the cytoplasm such as occur following stilbamidine and antimony therapy were not present. A few of the plasma cells had developed into giant forms nearly as large as megakaryocytes (fig. 1 D). The total number of plasma cells comprised but 1.0 per cent of the total marrow cells. Megakaryocytes, many showing platelet formation, were present in about normal numbers. Other marrow elements were not detectably abnormal.

On a check-up examination three and one-half months after the beginning of treatment the plasma proteins had fallen to 8.1 Gm. per 100 cc., with 5.0 Gm. albumin and 3.1 Gm. of globulin (table 5). The bromsulphalein test repeated as before showed but a trace of the dye remaining in the serum at 45 minutes. The alkaline phosphatase was 6.7 Bodansky units, calcium 10.6 mg. per 100 cc., and phosphorus 2.9 mg. Bence Jones proteinuria and albuminuria were not present.

Improvement in her general health continued during the following five months. The peripheral blood values became normal (table 1). Repeated bone marrow examinations failed to show abnormal numbers or types of plasma cells. The blood chemical values remained unchanged. Skeletal x-rays showed gradual recalcification of the vertebrae, pelvis and upper femora. She began to complain of lower abdominal pain radiating into her right thigh and examinations showed progressive anterior displacement of a fibroid uterus. A laparotomy was performed and the iliac vessels and mesocolon were infiltrated with a fleshy retroperitoneal tumor. Resection was attempted. She died two days later of uncontrolled hemorrhage one month after the beginning of urethane therapy. Pathologic examination of the resected tissue showed it to be a myeloma tumor.

*Case 2* A R. Unit No. C-19679. This 47 year old white divorced mill worker was referred to Duke Hospital by Dr. A. J. Tannenbaum of Greensboro on October 13, 1947. Her general health had been good until about two years previously when following a marital rift she developed malaise, loss of appetite, and became habitually worrisome. Cramps and pains about her muscles and joints developed during the

following months. In March, 1946, she found that her weight was ten pounds below her average. An anemia with blood values about 50 per cent of normal was discovered and it was thought that she improved for a time with vitamin and liver therapy. Two or three months before her hospital admission, she became more or less constantly uncomfortable due to sharp stabbing pains particularly about her shoulders and trunk. Her family physician after admitting her to a local hospital found that she had fever, anemia, albuminuria and skeletal decalcification. Two blood transfusions were given. Multiple myeloma was considered as a diagnosis but since Bence Jones protein could not be found in the urine a tentative diagnosis of hyperparathyroidism was made.

TABLE 2.—Case 2, A. R., C-19679, Hematologic Findings

Date 1947-48	Hgb	RBC	WBC	Hemato- crit	Reticulo- cytes	Plate- lets	Differential WBC and therapy

6/21	12.9	4.4	10600	40	1.0	1900	

Physical examination showed the patient to be a poorly nourished, chronically ill middle aged white woman. Pressure over the lower ribs was painful. The liver edge was palpable just below the costal margin. There were no enlarged lymph nodes or tumor masses.

Examination of the peripheral blood showed a normochromic, normocytic anemia (table 2). There was marked rouleau formation in the blood films. There was a large amount of protein in the urine and on some occasions a small amount of Bence Jones protein could be demonstrated. Serologic tests for syphilis were negative. The serum proteins were 8 Gm per 100 cc, with albumin 2.5 Gm and globulin 5.5 Gm. The blood calcium was 9.1 mg per 100 cc, phosphorus 3.8 Gm and the alkaline phosphatase 1.7 Bodansky units. A bromsulphalein test of liver function using 5 mg of the dye per kilogram of body weight showed 10 per cent retention after 45 minutes. A phenolsulphthalein test of renal function

showed an excretion of 40 per cent of the dye in two hours. Roentgen examination of the skeleton (fig. 2, A) showed generalized, punched-out destructive lesions in the skull, ribs, scapulae, spine and pelvis. There were questionable areas of bony destruction in the upper end of the right tibia. There was no collapse of the vertebrae. Bone marrow was obtained by aspiration from the sternum and from the spinous process of a lumbar vertebra. Thirty-five per cent of the marrow cells were immature and abnormal plasma cells (fig. 2, C).

FIG. 2. CASE 2, A. R. UNIT No. C 19679

- A Roentgenograms of skull showing multiple small areas of bony destruction before treatment
- B Repeat roentgenogram seven months after beginning of treatment showing no progression in lesions
- C Photograph of aspirated bone marrow ( $\times 600$ ) before treatment showing 35% atypical plasma cells
- D Photograph of clumped plasma cells in aspirated marrow three months after beginning of urethane therapy. Plasma cells were reduced to 4% with variation in size and altered staining reaction

The administration of urethane was started on October 20, 1947, giving 4 Gm. per day by mouth. She tolerated it well. On the fourth day of therapy a leukocytosis of 15,900 occurred but during the next month the WBC gradually fell to hover around 4,000. During her two weeks in the hospital she had a daily rise in temperature to 38–40  $^{\circ}$ C. At the end of this time bone pain was decreasing, she had begun to gain weight and was able to return home. She was seen thereafter at frequent intervals for check-up examinations. After a few more weeks her temperature remained normal. Her blood values improved progressively (table 2). The urethane was discontinued after two months of continuous therapy with a total dose of 240 Gm. had been given. Re-examination of the bone marrow three months after the beginning of therapy showed that the plasma cells were reduced to 4 per cent. The remaining marrow elements were not notably abnormal.

Seven months after the start of treatment she had gained 20 pounds in weight. She considered her general health better than it had been for several years. She was able to do all of her work at home except the heaviest tasks. Physical examination at this time showed no abnormalities. Bence-Jones protein could not be demonstrated in the urine. The serum proteins were 8.8 Gm. per 100 cc. as before but the albumin was now 4.4 Gm. and the globulin 3.6 Gm. (table 5). Repeat x-ray films of the skull showed that there had been no progression in the bony lesions. Multiple areas of rarefaction remained (fig. 2, B).

Bone marrow was aspirated from the sternum for the third time. The cellularity was within range of normal with a total white cell count of 232,000. Four per cent of the cells were plasma cells. These varied in size to an unusual degree from about 10 to 50 microns in diameter (fig. 2, D). Their cytoplasm was somewhat indefinite as to boundary and their staining reaction varied from dark to pale blue from cell to

cell. Basophilic granulation was not present. The nuclear chromatin stained densely and occurred in coarse clumps. The appearance and distribution of the remaining marrow elements was not abnormal.

A check up examination at eight months showed no essential changes. She had returned to full time work in a hosiery mill. The blood values had continued to improve (table 2). The urine contained a trace of Bence-Jones protein. A phenolsulphonthalein test showed an excretion of 35 per cent of the dye in two hours. The alkaline phosphatase activity had become slightly elevated.

A few weeks later she felt feverish for a day or two. Examination showed more Bence-Jones protein in the urine and an increased number of plasma cells in the bone marrow. She was given 120 Gm. of urethane in a month's time. On a check up examination thirteen months after urethane therapy was first begun she was working full time and there was no evidence of further relapse.

Case 3, S J C Unit No C-28643. This 54 year old electrician was admitted to Duke Hospital on February 23, 1948, for the investigation of anemia, suspected heart and renal disease. He had been well and working regularly until four weeks previously when within a period of a few days he became weak, pale and unable to exert himself physically without becoming short of breath. He had pain about the lower

ribs on the right side that was made worse by breathing and coughing. His symptoms became progressively worse. During the week preceding his hospital admission he was quite drowsy in the afternoons, had little appetite, was often nauseated and vomited once or twice. He found that he slept better at night when using two or three pillows. Early in the morning of the day of his hospital admission he was awakened from sleep by acute dyspnea.

Physical examination disclosed a pale, overweight white male, obviously ill. His blood pressure was 135/80 mm. of mercury. Two small flame shaped hemorrhages were visible near the right optic disc. His

FIG. 3. CASES 3 AND 4

A. Case 3, S. J. C. Unit No. C-28643. Roentgenogram of skull before treatment showing multiple large and small areas of bony destruction.

B. Case 4, O. M. R. Unit No. C-17783. Roentgenograms of skull showing similar but less extensive bony destruction.

C and D. Photograph and lateral roentgenogram of myeloma cell tumor of sternum, case 4.

heart was slightly enlarged. There was a moderately loud systolic murmur at the apex and the first heart sound was doubled. The liver edge was felt 5 cm. below the right costal margin. The tip of the spleen was palpable. There was slight pitting edema at the ankles.

Laboratory studies showed that he had a severe normochromic, normocytic anemia with immature granulocytes and nucleated red blood cells in the circulating blood (table 3). In fresh and stained films there was conspicuous rouleaux formation. Serologic tests for syphilis were negative. Several urinalyses showed heavy proteinuria and granular casts but no Bence Jones protein. Blood chemical determinations showed the NPN to be 35 mg. per 100 cc., total proteins 8.5 mg. with albumin 3.8 Gm. per 100 cc. A phenolsulfonphthalein test showed impaired renal function: 5 per cent of the dye appearing in the urine in fifteen minutes and a total of 40 per cent in two hours. The bromsulfalein test of liver function, using 5 mg. of the dye per kilogram of body weight, showed only a trace of the dye appearing in the

tumor in October 1947. During the next few months he had far less pain about the sternum but the tumor mass did not decrease in size.

He was recalled for a check up examination on April 12, 1948. At that time he complained of more pain than on previous occasions, especially when he exerted himself physically. The discomfort was noted particularly over the left upper humerus, about his ribs and sternum. Physical examination showed no obvious changes. Examination of the blood showed that there had been some deterioration in the blood values (table 4). A specimen of bone marrow from a spinous process was again examined and 39 per cent of the cells were abnormal plasma cells. The serum proteins had risen to 10.1 Gm. per 100 cc. with albumin 2.9 Gm. and globulin 7.2 Gm. (table 5). X-ray films of the chest, skull, left humerus and sternum showed little definite extension of the areas of previous bone destruction.

The administration of urethane was started on April 13, 1948, with a dose of 4 Gm. per day by mouth. During the next four weeks his pain became gradually less except about an area on the lateral chest wall where a rib had apparently been fractured during the maneuvers incident to making roentgen films. Examination of the blood showed that a leukopenia had developed. An increased number of plasma cells was still present in the bone marrow but they were now larger in size and their cytoplasm more densely stained. Their nuclei were extremely eccentric and the chromatin was aggregated into dense clumps.

The administration of urethane was continued at home under the supervision of his family physician. The leukopenia persisted but became no more severe. Without notable trauma another rib fracture occurred and severe pain developed about one hip. He was admitted to his local hospital and the pain subsided at bed rest.

The urethane was used somewhat irregularly. On a check up examination three months after the beginning of treatment he considered himself definitely improved. Urethane was discontinued and for two months he was virtually free of symptoms. Skeletal pain then gradually reappeared and he did not return for further treatment. He died at home seven months after the beginning of urethane therapy.

## DISCUSSION

Multiple myeloma is a malignant disease resulting from the excessive proliferation of abnormal plasma cells within the bone marrow. The clinical course is variable, as judged by the length of survival of individual patients, but uniformly progressive and ultimately fatal. There is no evidence that real spontaneous remissions occur.

Therapy in the past has been unsatisfactory. The commoner agents useful in the treatment of the lymphomatous diseases, roentgen irradiation, radioactive phosphorus, and nitrogen mustard compounds, have little demonstrable effect beyond relieving pain in some individuals. Stilbamidine, pentamidine, and antimony compounds have been reported to relieve skeletal pain and produce apparently specific granular changes in the cytoplasm of the myeloma cells.

The 4 patients included in this study illustrate many of the variable clinical features of multiple myeloma. In Cases 1 and 3 the disease was rapidly progressive. In the other two it was progressing slowly. Case 4 was thought at first to have a solitary myeloma cell tumor of the sternum. Examination of marrow obtained from other bones showed the disease to be generalized. The major effect of roentgen therapy to the sternal tumor was relief of pain. In Case 1 the predominant feature was a devastating skeletal disease. Metastatic carcinoma was considered a good possibility, as it frequently must be, in the differential diagnosis. In Case 3 symptoms of cardiac failure were precipitated by anemia. The presence of renal disease complicated the diagnostic problem. The finding that the anemia did not result from renal failure, however, and the occurrence of immature granulocytes in the circulating blood led to a bone marrow examination and the discovery of plasma

cell overgrowth. There was no skeletal pain and roentgen films showed significant abnormalities only in the skull. In all patients the crucial diagnostic information was provided by examination of the bone marrow.

The treatment adopted in these cases was entirely empiric. The urethane was given in divided doses by mouth in the form of an elixir or syrup. All four of the patients tolerated the chemical exceptionally well with virtually no gastrointestinal symptoms. During the first three to four weeks they were given 4-6 Gm. per day. Three patients developed leukopenia following which the dose was reduced to about 2 Gm. daily or temporarily suspended. Further fall in the white cell count did not occur. The urethane was given over a period of about two months and then discontinued. The total dose per patient varied from 120-240 Gm. Treatment and post-treatment periods of observation ranged from seven to thirteen months. Two patients relapsed and were given a second course of therapy.

All 4 patients showed much the same type of response to urethane. General clinical improvement appeared during the second and third week of therapy when skeletal pain and fever began to subside. Physical activity soon became tolerable within the obvious limitations imposed by skeletal disease. The two patients with most extensive areas of skeletal destruction were able to perform ordinary activities and do light work within four to six months of the start of treatment without discomfort.

A normochromic, normocytic anemia with hemoglobin values ranging from 7.2 to 11.0 Gm. was present in all 4 patients. In 2 cases, immature granulocytes and nucleated red cells were present in the circulating blood. An abrupt but transient leukocytosis was noted in 2 patients on the fourth day of urethane administration, possibly the result of chemical stimulation of cell division. Leukopenia with white cell counts ranging between 2600 and 4400 developed in about three to four weeks. Reduction in the urethane dosage to around 2 Gm. per day was sufficient to prevent the development of more serious white cell depression. In about the same time evidence of marrow crowding subsided, immature granulocytes and nucleated red blood cells disappearing from the circulating blood. Progressive fall in hemoglobin and red cell values ceased after one to two weeks of urethane but notable regeneration of blood did not begin before four to six weeks. There was gradual improvement in the blood values toward normal for several weeks following the termination of urethane therapy.

The initial bone marrow aspiration showed in all cases the massive proliferation of abnormal plasma or myeloma cells diagnostic of multiple myeloma. Repeated examinations of bone marrow in Cases 1, 2, and 3 obtained from different sites after urethane therapy revealed a striking quantitative decrease in the number of these cells. A characteristic change in myeloma cell morphology occurred, also, with urethane administration. Some became monstrous in size recalling the changes observed in plant seedlings.<sup>1</sup> Others as observed in spread films made from aspirated marrow tended to adhere together in small compact clumps. Variation in cell size, densely staining cytoplasm, and eccentric and pyknotic nuclei were general features of those myeloma cells which persisted after urethane administration. Basophilic granulation of the cytoplasm<sup>2-4</sup> did not develop.

The initial blood chemical values (table 5) were typical of those occurring in multiple myeloma. In Case 1, the serum calcium was elevated to 12.4 mg per 100 cc, but in all other instances it was normal. Phosphatase activity, determined in 3 cases before treatment, was low or normal and in 2 patients with extensive skeletal disease it increased slightly after urethane administration.

Hyperglobulinemia with reversal of the albumin globulin ratio was present initially in all cases. In Cases 1, 2, and 3 the serum globulin fell markedly and the albumin rose slightly to restore a normal ratio of these protein components during the period of after treatment follow-up. The serum proteins were studied electrophoretically in these 3 cases before and after urethane treatment, and will be reported in detail later by Dillon and Rundles.<sup>28</sup> In Case 1, 49 per cent of the total protein showed the electrophoretic mobility of gamma globulin. Four months after the beginning of urethane therapy protein with this mobility was reduced to 18.0 per cent. In Case 2, a similar increase in the gamma globulin occurred, amounting to 45.7 per cent of the total. Seven months after urethane administration was begun this component was reduced to 23.8 per cent. In Case 3, the initial electrophoretic study showed that the abnormal protein had a boundary lying between the beta and gamma globulins, the M variety of protein abnormality in multiple myeloma described by Gutman, et al.<sup>29-30</sup> The total percentage of M and gamma globulins before treatment totaled 45.2 per cent. Three and one-half months later these fractions had fallen to 33.4 per cent.

Renal disease<sup>31-32</sup> as evidenced by proteinuria of greater or less degree was present in all of the patients with multiple myeloma. Bence-Jones protein was demonstrated in the urine of two. None had nitrogen retention. The excretion of phenol-sulphonphthalein dye was impaired in two patients before treatment was started. During the weeks following urethane administration nitrogen retention did not develop, albuminuria tended to subside and Bence-Jones proteinuria was less often demonstrable.

Serial roentgen films taken over a period of months following urethane therapy showed no progression in the destructive skeletal lesions which are so prominent a feature of multiple myeloma. The subsidence of bone pain occurring at bed rest, followed in a few weeks by the ability to tolerate moderate physical activity, suggested improvement in skeletal support as a result of therapy. The slight increase in phosphatase activity suggests some attempt at bony repair. There was definite roentgen evidence of recalcification in one patient 6 months after the beginning of treatment. Bony softening persists without doubt for some period of time, and perhaps indefinitely. Roentgen films of the skeleton thus provide no means for judging the early response to therapy, but the chronicity of the lesions does caution against the too rapid expansion of physical activity.

Evidence has been presented to show that the administration of urethane to patients with multiple myeloma alters the fundamental abnormalities of the disease in a selective and beneficial way not possible by previously available therapeutic agents. The present report concerns only the early responses to treatment. The long term results remain to be studied. At this time we have no doubt that urethane therapy has already prolonged life in 2 cases in whom the disease was

rapidly progressive Relapses of the disease may not occur for as long as six months or longer after discontinuation of therapy Whether interrupted or continuous therapy will eventually prove most desirable is a matter of conjecture To detect reactivation of the disease so that therapy can be given again when indicated will require serial blood examinations, frequently repeated bone marrow studies with attention to the number and appearance of the plasma cells, quantitative study of proteinuria, and serial studies of the serum proteins preferably by electrophoretic methods The effect of urethane therapy offers a new tool in investigating the complex protein and cellular abnormalities which characterize the disease

### CONCLUSIONS

Four patients with multiple myeloma have been treated with urethane (ethyl carbamate) for eight to ten weeks in total doses of 120-290 Gm and observed over periods ranging from seven to thirteen months Striking benefit relating to all aspects of the disease was observed Fever, skeletal pain and acute symptoms subsided after two to four weeks of therapy In individuals with severe anemia, immature granulocytes and nucleated red cells disappeared from the circulating blood, and over a period of several weeks, the blood values improved greatly toward normal Abnormal plasma or myeloma cells decreased quantitatively in the bone marrow and underwent morphologic changes indicative of retarded or arrested growth The serum protein abnormalities characteristic of multiple myeloma became less pronounced or disappeared as did the albuminuria and Bence-Jones proteinuria Serial roentgenograms of the skeleton showed no progression in the destructive lesions There was little evidence of skeletal recalcification, however, for four to six months after treatment The long term results of urethane therapy in multiple myeloma, the liability to exacerbation of the disease, the effectiveness of subsequent courses of urethane therapy, the course of the associated renal disease, the extent of skeletal recalcification and repair, etc., are matters for further study

# THE RESPONSE OF EOSINOPHILS IN THE GUINEA PIG TO SENSITIZATION, ANAPHYLAXIS AND VARIOUS DRUGS

By MAX SAMTER, M D

## I REVIEW OF EARLY CONCEPTS AND EXPERIMENTAL STUDIES SCOPE

THE HISTORY of the eosinophilic polymorphonuclear leukocytes (referred to as eosinophils throughout this study) has few landmarks. In 1846, Wharton Jones<sup>1</sup> gave the first reliable description of 'coarse granules' in colorless blood cells. Their morphologic characteristics are so striking that early (Max Schultze<sup>2</sup>) and recent (Cunningham and Tompkins<sup>3</sup>) observations differ only in insignificant detail. Paul Ehrlich<sup>4</sup> established in 1879—in his *farbenanalytischen Untersuchungen*—the distinctive mark of the fixed cell, namely, the elective staining of its  $\alpha$ -granules with acid dyes.

Since then, innumerable data on the occurrence of eosinophils have been collected. A comprehensive survey prepared by Emil Schwarz<sup>5</sup> in 1914 listed in its 653 pages a bibliography of 2758 publications. Yet while Schwarz and others defined the occurrence of eosinophils under various clinical and experimental conditions, they added little to our knowledge of their function. The association of eosinophilia with a variety of unrelated disorders is still not well understood (Bethell, Sturgis, Rundles and Meyers<sup>6</sup>).

Experimental research has been retarded for two reasons. The first reason is the direct result of the controversy about the site of origin of the eosinophils. Authors who regard the bone marrow as their only source, will interpret circulating eosinophils as the necessary link between their site of formation and the tissues in which they are eventually found. Authors who accept the concept of the development of eosinophils at sites other than the bone marrow, have concluded that the same circulating eosinophils represent an overflow, or have been discarded from the tissues in which they have developed.

Ehrlich<sup>7</sup> committed himself to the hypothesis that eosinophils are formed in the bone marrow and are distributed by the blood stream. His concept initiated a lively scientific controversy about the question of the homoplastic or heteroplastic origin of eosinophils which fills the early volumes of *Folia Haematologica* (Ascoli<sup>8</sup>, Pappenheim<sup>9</sup>, Weidenreich<sup>10</sup>, Maximow<sup>11</sup>, Downey<sup>12</sup> and Ringhorn<sup>13</sup>).

Biggart<sup>14</sup> has summarized some of the controversial questions: whether or not blood and tissue eosinophils are identical; whether there is local multiplication of eosinophils; assuming that there is only one type of eosinophil, what causes their emigration from the blood into the tissues; what finally are the relations between bone marrow and tissue eosinophilia?

Several of these questions have been studied by Opie<sup>15</sup>, Schlecht and Schwenker<sup>16</sup>, Weinberg and Seguin<sup>17</sup> and Homma<sup>18</sup>. The majority of investigators have recognized the bone marrow as the source of the eosinophils which appear in the peripheral circulation, but a final agreement between the dissenting factions has not been reached. Cooke<sup>19</sup> has only recently claimed that the discrepancy between the number of eosinophils in blood and tissue are sufficient reason to assume the existence of two distinct

From the Department of Medicine and the Allergy Unit, College of Medicine, University of Illinois at Chicago, Ill.

The expenses of this investigation were defrayed in part by funds from the Allergy Club, Chicago, Ill.

types of eosinophils. And while Homma<sup>18</sup> emphasizes the fact that no intermediary stages exist between small lymphocytes, large lymphocytes and macrophages on one side eosinophils on the other side Ringoe<sup>20</sup> concludes "Tissue eosinophils are derived from various sources, lymphocytes large mononuclears, plasma cells and adventitial cells being regarded as parent cells".

In spite of the existing disagreement as to the site of origin of eosinophils, the intimate relationship of eosinophilia to certain phenomena of hypersensitivity has been established beyond doubt (Hajos,<sup>21</sup> Hajos and Mazgon,<sup>22</sup> Campbell, Drennan and Rettie,<sup>23</sup> and D. H. Campbell<sup>24</sup>). Its mechanism, however, as well as its function and meaning are still obscure. It is surprising to note that experiments of very similar nature have led investigators to diametrically opposed conclusions. Analysis of the literature reveals what must be regarded as the second reason for the hesitant progress of experimental research on eosinophils: a multitude of experimental procedures in a field where minimal changes in technic are bound to cause major changes in results.

It will become necessary, therefore, to apply the rigid standards which distinguish immunologic research in general to research on eosinophils which are part of the immuno-reactions of the organism. Study of eosinophilic response requires a uniform experimental technic which includes a uniform species, a uniform antigen, and a uniform route of administration. Accordingly, the first section of this investigation discusses criteria for the choice of the experimental animal, the choice of a suitable antigen, its dose, and the route by which it is administered.

## II. GENERAL CONSIDERATIONS

### *Choice of the Experimental Animal*

Review of the literature shows that guinea pigs have been preferred for study of experimental eosinophilia although other species have been investigated. Data about hematologic changes in rabbits and dogs, however, are scanty and controversial. White rats—used by Homma<sup>18</sup> in an attempt to correlate eosinophils in bone marrow, blood and tissues after injection of parasites and parasitic material—have the disadvantage that they are very unresponsive to anaphylactic sensitization. If one intends to demonstrate the allergic state of the sensitized animal by the symptoms of anaphylaxis, guinea pigs are most suitable and were therefore employed.

The guinea pigs were bought at random and raised until they weighed between 400 and 450 grams at the time of the experiment. It appeared advisable to eliminate larger guinea pigs, since Opie<sup>15</sup> in his early studies had shown that guinea pigs tend to develop a spontaneous eosinophilia which increases with increasing weight. The cause of this eosinophilia has not been established although parasitic infestation such as by *megastoma entericum* in the small intestines and *infusoria* in the cecum has been suspected. The diet consisted of oats supplemented by lettuce and carrots, no added water was given. The average differential count prior to sensitization of the 482 animals used in our studies was as follows: Lymphocytes 42 per cent, neutrophils 55 per cent, monocytes 3 per cent. Eighty-two per cent of the animals had no eosinophils, 14 per cent (68) had 1 per cent. The remaining guinea pigs which had up to 7 per cent eosinophils were classified as a separate group.

They are included and discussed in section VI. The figures at which we have arrived differ slightly from those quoted by other observers, it is felt that this difference may be due, in part, to differences in strains used by this author. The figures listed in Klieneberger's<sup>15</sup> manual, however, are based on too few animals to serve as a satisfactory base line.

Each experimental group consisted of either six or eight animals, male or female, and no sex distinction was made in our studies.

### *Choice of the Antigen*

Selection of a suitable antigen became an interesting problem since Campbell<sup>24</sup> correlated the insolubility of the antigen as well as the presence of -SH groups with its ability to elicit eosinophilia. The literature is full of curious contradictions. Homma<sup>18</sup> reported that coagulated egg albumen and fibrin failed to produce a significant tissue eosinophilia in white rats. Schlecht,<sup>25</sup> on the other hand, was

able to observe (in two experimental animals) extraordinary increase in eosinophils after injection of a 2 per cent fibrin solution, neither author gives sufficient data about the preparation of the antigen to permit evaluation of the discrepancies. We have conducted a considerable number of preliminary experiments in order to establish variations of the response of eosinophils in guinea pigs to antigens of various solubility and antigenicity as expressed by the severity of anaphylactic reactions following re-injection. The antigens tested included fibrin, several fractions of egg white prepared for us by Dr. A. G. Cole, and hapamine (histamine conjugated with a despeciated horse serum globulin through azo linkage) a compound reported to be a poor antigen (Cohen and Friedman<sup>26</sup>).

Table I summarizes some of the results. The animals had been sensitized twenty-one days before the test by intraperitoneal injection of 75 cc. of a 1 per cent solution of the protein under investigation. They were re-injected intracardially with the homologous antigen. Differential counts were taken of the surviving animals three hours and twenty hours after re-injection. The percentage of eosinophils found after twenty hours (when the maximal eosinophilia had been reached) is

listed in table 1 Guinea pigs sensitized and reinjected with ovalbumin show the lowest percentage of eosinophils, but the highest incidence of fatal reactions, while guinea pigs sensitized and reinjected with hapamine develop a considerable eosinophilia in spite of the absence of fatal shock. The anaphylactic reaction as well as the eosinophilic response are phenomena of sensitization, since neither can be elicited by the introduction of a nonspecific protein, it is evident from our experiments, however, that the effectiveness of a given protein in achieving anaphylactic sensitization does not parallel its ability to produce eosinophilia.

The antigen which was finally selected for this study, horse serum, combined reliable anaphylactic antigenicity with satisfactory ability to produce eosinophilia. With few exceptions, therefore, which are labeled as such, horse serum was used as sensitizing and shocking antigen throughout the experiments. One group of six guinea pigs was sensitized and shocked concurrently with each series of experiments. No conclusions were drawn unless fifty per cent of the controls succumbed to fatal anaphylactic reactions.

The animals which were sensitized by intraperitoneal injection of horse serum with few exceptions did not develop eosinophilia prior to reinjection of the specific antigen. Animals which had more than 1 per cent eosinophils prior to reinjection were excluded from the experiments.

Von Pirquet and Schick<sup>23</sup> had suspected that if a large amount of antigen is injected, a portion of it might persist, unaltered, throughout the period of sensitization, combine with the antibodies which have formed during this period and account thus for the symptoms of serum sickness. Since eosinophils appear in the peripheral circulation subsequent to antigen antibody reactions, it seemed conceivable that the injection of a sizeable dose of horse serum might, similarly, cause eosinophilia. However, in a group of six guinea pigs which were given a sensitizing dose of 20.0 cc. of horse serum, none developed eosinophilia prior to reinjection of the specific antigen.

### *Route of administration*

A survey of experimental research on eosinophils indicates that little attention has been paid to the route by which the antigen was administered. It is a common occurrence to find intradermal, intramuscular, intraperitoneal, intravenous and intracardial administration used indiscriminately within the same group of experiments as if the route of administration were of no consequence. Even if one disregards fundamental objections (Heidelberger, Treffers and Freund,<sup>24</sup>) it is quite obvious that reinjection of antigen into a shock tissue, e.g., the skin, with a resulting local antigen-antibody reaction, creates experimental conditions which cannot be compared with, for example, vascular reinjection. Applied to the study of eosinophils, this variety of routes used for the administration of the antigen makes it understandable why the question has not been adequately answered whether the eosinophilic response to reinjection of antigen is due to the antigen per se, the antigen-antibody reaction, the shock syndrome, or the liberation of substances during the immunologic processes. The experiments of Weinberg and Seguin<sup>17</sup> are a case in point. The results of their observations are significant for

certain phases of the mechanism of the eosinophilic response which will be discussed later, but they also demonstrate clearly that results obtained after subcutaneous, intraperitoneal, and intravenous reinjection are not comparable

Although it is possible to sensitize guinea pigs by any parenteral route, the intraperitoneal injection is not only most convenient but known to give, for this particular antigen, consistent anaphylactic sensitization. The reason for this is not fully understood although it has been suggested that the copious lymphatic drainage of the peritoneum, and a resulting efficient elaboration of antibodies, might be responsible. The sensitizing dose of the antigen, therefore, has been given intraperitoneally.

The route of readministration on the other hand can influence the outcome of the experiments in several ways. The speed of absorption of reinjected protein varies with the site of administration. The site of the injection determines, therefore, the time interval between the introduction of the antigen and the changes which it causes. If, furthermore, reinjection is made into sensitized shock tissue, e.g., the skin, it becomes questionable how much non-neutralized antigen reaches the rest of the animal. Accordingly, Weinberg and Seguin,<sup>17</sup> who reinjected the majority of animals intravenously and intraperitoneally, came to conclusions almost irreconcilable with those of Hajos<sup>21</sup> who administered the antigen intramuscularly or by inhalation. The intravascular reinjection affords an immediate distribution of the antigen throughout the animal and prevents its retention at the site of administration. Intracardial rather than intravenous administration was used by us because of its technical advantages, it requires, however, that a post-mortem examination be done on each animal which dies during or shortly after the injection, since the occasional perforation of the heart muscle with massive hemorrhage might simulate the asphyctic death of acute anaphylaxis.

#### *Technic of the Eosinophil Count*

The technic of preference for the study of eosinophils is the absolute eosinophil count (Zappert,<sup>20</sup> Discombe,<sup>21</sup> and Randolph<sup>22</sup>)

Unfortunately, the amount of blood which can be obtained for repeated studies from the ear veins of the guinea pig is not sufficient to make absolute blood counts as a routine procedure. This fact has disturbed various investigators (Opie<sup>15</sup>), but it has been shown that the changes in total white count during this particular type of experiment are not of sufficient magnitude to discredit the significance of findings based on changes in differential count alone. Reliability of differential counts, however, depends on uniform technical handling. The blood has to be transferred from the ear without pressure and is spread evenly into a thin film between two coverslips. Even under the most favorable circumstances, this is not always successfully accomplished. In our experiments a considerable number of preparations had to be discarded because distribution or preservation of leukocytes proved unsatisfactory. The coverslips were stained with Wright's stain and, after drying, attached to a labeled slide with Canada Balsam. Blood counts taken before reinjection of antigen and at fifteen, thirty, forty-five, and sixty minute and then at hourly intervals for twenty-four hours after reinjection of antigen demon-

strated that there is a time lag between administration of antigen and cellular response. The maximal eosinophilia was not reached before a lapse of twelve to twenty-four hours after reinjection. This observation, found in early work and re-emphasized by Hajos,<sup>21</sup> is of great theoretical interest and has not received the recognition which it deserves.

### III RESPONSE OF SENSITIZED GUINEA PIG TO REINJECTION OF SPECIFIC ANTIGEN

*Experimental problem.* It is difficult, if not impossible, to produce uniform sensitization in any given group of experimental animals. This difficulty is well known and represents one of the most serious obstacles to quantitative evaluation of results. Rich,<sup>22</sup> for instance, in his studies on the pathogenesis of rheumatic fever and periarthritis nodosa states: "This native, individual difference in reactivity, which not only determines whether a given sensitized individual will, on contact with the antigen, develop a hypersensitive reaction but also determines in what tissue the hypersensitive reaction will occur, has, in all probability, an hereditary, constitutional element." The variation in the eosinophilic response is even greater than the differences in anaphylactic reactivity; we have no indication that the mechanisms of either are related. Our experimental procedure ascertains within reasonable limits the anaphylactic antigenicity of the antigen used in each particular series of experiments. The ability of the same antigen to elicit an eosinophilic response in sensitized guinea pigs after intracardial reinjection remains to be established before an analysis of factors which influence such response can be attempted.

*Experimental procedure.* Thirty-six guinea pigs were sensitized by intraperitoneal injection of 1 cc. of horse serum without preservative. Twenty-one days later, 28 guinea pigs were reinjected with 0.75 cc. of horse serum intracardially. The 8 remaining guinea pigs were injected with 0.75 of a 1 per cent solution of crystallized ovalbumin. Differential counts were obtained of all animals prior to reinjection, of the surviving animals three hours and twenty hours after reinjection.

*Results.* The percentage of eosinophils observed twenty hours after reinjection of horse serum in a series of 12 guinea pigs is listed in column 1, table 2. None of the guinea pigs had eosinophils prior to reinjection. Subsequent to reinjection, the figures range from 0 to 26 per cent. Only one animal failed to show an eosinophilia. Only 2 out of the 8 guinea pigs injected with crystallized ovalbumin developed an eosinophilia of 2 per cent and 3 per cent respectively. Differential blood count of the remaining 6 guinea pigs showed the changes in lymphocytes which are known to follow the injection of protein, but no eosinophils. We have omitted the three hour counts from the table, since they do not add any essential information. Their possible significance will be discussed in Section V.

*Conclusions.* Preliminary experiments summarized in table 1 had shown that the nature of the antigen determines, in part, the response of the eosinophils in the sensitized and reinjected guinea pig. Response is independent of severity of anaphylactic symptoms. Regardless of its extent, however, response depends in all cases on reintroduction of the specific antigen. Injection of a nonspecific protein in sensitized guinea pigs does not result in eosinophilia. The response also varies

within a wide range in a series of animals sensitized and reinjected with the same antigen, again, the appearance of eosinophils in the peripheral circulation is a specific response whether the final level reached be low or high. Reasons for these variations are not known.

#### IV RESPONSE OF THE SENSITIZED GUINEA PIG PROTECTED BY ANTIHISTAMINE DRUGS TO REINJECTION OF SPECIFIC ANTIGEN

*Experimental problem* Introduction of antihistamine drugs, the clinical significance of which is still under investigation (Feinberg<sup>14</sup>), has been instrumental in widening the scope of investigative work in allergy. It permits the study of animals of maximal sensitivity which, thus protected, survive reinjection of the specific antigen.

antigen Synthesis of compounds which combine antihistaminic and sympathetic action has made it possible to re-examine the concepts of workers who, like Hajos,<sup>21</sup> emphasize the prominence of the autonomic nervous system in eosinophilia We wish to state that this part of our study would have been incomplete, if not impossible, without the advice and the generosity of Dr E R Loew who not only supplied the necessary chemicals and the data on their comparative potency, but also consented to integrate our preliminary and final experiments on the response of the eosinophils into his own which tested the antianaphylactic action of the drugs

The first series of experiments was carried out on animals protected with  $\beta$  dimethylaminoethyl benzhydryl ether-HCl benadryl

(Loew<sup>22</sup>)

The potency of this substance is about one-twentieth of a comparable French antihistamine drug, neoantergan (N-p-methoxybenzyl-N-dimethylaminoethyl aminopyridine)

In subsequent experiments, a number of alkyl derivatives of  $\alpha$ -naphthyl-methyl  $\beta$ -chloroethylamine and of 2-bi-phenoxyethyl- $\beta$ -chloroethylamine were used \* Achenbach and Loew<sup>26</sup> have shown that the histamine antagonism produced by these compounds is of an order similar to the one afforded by benadryl and its relatives, but while the latter enhances the pressor response to epinephrine in animals, the former exert epinephrine blocking action They reverse, for instance, the pressor effect of epinephrine in dogs The following compounds were used and they are designated by their test numbers

SY 14  $\alpha$ -naphthylmethylethyl- $\beta$ -chloroethylamine HCl

SY 18  $\alpha$ -naphthylmethylethyl- $\beta$ -bromoethylamine HBr

\* Those compounds were synthesized and made available to us by Drs G Rieveschl Jr R Fleming and W R Coleman of Parke, Davis and Company Detroit Michigan

SY 27  $\alpha$  naphthylmethylisopropyl- $\beta$ -chloroethylamine HClSY 18  $\beta$ -2-biphenyloxyethyl- $\beta$ -chloroethylamine HCl

Antihistamine activity of SY 14, SY 28 and SY 27 equals approximately that of neoantergan, while SY 18, like benadryl shows only one-twentieth of the protective action produced by neoantergan

*Experimental procedure* Eighty guinea pigs were sensitized with horse serum in accordance with the technic described in Section II. Twenty-one days after the sensitizing injection, they were divided into seven groups. The first group (15) was given benadryl, 5 mg /Kg in aqueous solution, thirty minutes prior to reinjection. The second group (15) was given SY 14, 15 mg /Kg in aqueous solution, thirty minutes prior to reinjection. The third group (15) was given SY 18, 15 mg /Kg in aqueous solution, thirty minutes prior to reinjection. The fourth group (10) was given SY 27, 15 mg /Kg in aqueous solution prior to reinjection. The fifth group (10) was given SY 28, 15 mg /Kg in aqueous solution thirty minutes prior to reinjection. The sixth group (10) was given benadryl, 5 mg /Kg in aqueous solution, without subsequent reinjection of horse serum, the seventh group (10) was given SY 14, 15 mg /Kg in aqueous solution without subsequent reinjection of the antigen. The antihistamine drugs were given subcutaneously or intraperitoneally. The last two groups were included in order to establish whether antihistamine drugs per se had any influence on the differential count of the guinea pig. Doses used were suggested by Dr. Loew and provided satisfactory protection against fatal anaphylactic reactions. It may be noted that the same dose was used for SY 14, SY 28 and SY 27. Quantitative studies would have to make allowance for the higher molecular weight of the bromide. Blood counts were taken three hours and twenty hours after reinjection of horse serum, or, in the last two groups, after injection of the antihistamine drug.

*Results* The percentage of eosinophils observed twenty hours after reinjection of horse serum in sensitized guinea pigs which were protected by five different antihistamine drugs against fatal anaphylactic reactions is listed in columns 3, 4, 5, and 6, table 2. The corresponding figures for the two groups of sensitized guinea

pigs which were injected with antihistamine drugs only, without subsequent re introduction of the antigen, are found in table 2a. The number of animals reported is somewhat lower than the number of those sensitized. This is due to loss of animals which for various reasons, died during or after sensitization.

The most outstanding findings in this series of experiments is the fact that the antihistamine drugs, while they block the anaphylactic reactions in the sensitized and shocked guinea pig, do not abolish the eosinophilic response. If normal distribution of the eosinophilic response could be assumed (which in view of our data is not justified) one could calculate that any difference which exists in eosinophilic response of animals protected by various antihistamine drugs is obliterated by the exceedingly high variability of such a response. This is obvious in the averages and standard errors listed in table 2a. Other types of distribution which have been tested lead to identical conclusions. Nevertheless, statistical analysis does not deny the possibility that drugs which combine histamine antagonism with sympathicolytic action, enhance the eosinophilia found in the peripheral blood twenty hours after reinjection of the antigen in sensitized guinea pigs. The administration of benadryl alone, without subsequent reinjection of the antigen, produced only minor changes in three out of six animals, the percentage of eosinophils observed after administration of SY 14 without subsequent reinjection of antigen remained below the average of reinjected guinea pigs, but showed sufficient increase to make further discussion necessary.

*Conclusions* It has been repeatedly stated that antihistamine drugs represent a tool to test, extend, or restrict the histamine theory of allergy (Mayer<sup>27</sup>), in which eosinophils have been included (Code<sup>28</sup>). Ratner<sup>29</sup> maintains that validity of the histamine concept has yet to be established. However, the fact that eosinophilic response is not abolished by antihistamine compounds lends itself to several interpretations.

If eosinophilic response is not due to release of histamine, it could not be expected to be altered by antihistamine drugs. If, on the other hand, liberation of histamine or histamine-like substances was the direct cause of appearance of eosinophils in the circulation, it must be assumed that antihistamine drugs fail to act on the underlying mechanism. This is conceivable, since various effects of histamine, e.g., its action on gastric secretion, are not uniformly influenced by antihistamine drugs. In the latter case, one could expect that eosinophilic response in protected animals would exceed the response in unprotected animals since more histamine—blocked from its pharmacologic action on smooth muscles and capillaries—might be available. It might be reasoned—paradoxical as it seems—that antihistamine drugs should exaggerate those effects of histamine against which they do not protect. As a matter of fact, the administration of antihistamine drugs alone might cause such effects as soon as the amount of histamine which they displace and divert exceeds the physiologic threshold, it is this consideration which led us to study the action of antihistamine drugs per se without subsequent re injection of antigen on the eosinophils in the guinea pig.

The mechanism of histamine activity, i.e., its rapid change from an inactive into an active form, is insufficiently understood. By the same token, the action of anti

histamine drugs has not yet been explained. We are aware that our findings that antihistamine drugs do not abolish the eosinophilia which follows an antigen antibody reaction in the guinea pig neither confirm nor disprove the possibility that histamine participates in its development.

The action of antihistamine drugs with sympathicolytic activity is of interest in view of the known fact that epinephrine decreases or abolishes an existing eosinophilia (Schwenker and Schlecht<sup>40</sup>), or reduces the eosinophilia which follows reinjection of specific antigen (Campbell<sup>24</sup>). Campbell has concluded from his experiments that epinephrine inhibits eosinophilia because it eliminates the shock syndrome without interfering with the antigen antibody reaction itself. The same statement, however, applies to antihistamine drugs which have no inhibiting effect on eosinophilic response. We feel that our concept of the importance of shock in the mechanism of the eosinophilic response requires a careful analysis and, probably, revision.

#### V. ROLE OF SHOCK IN PRODUCTION OF PERIPHERAL EOSINOPHILIA

*Experimental problem.* The importance of shock in the mechanism of the eosinophil response has been suggested by many authors, notably by Hajos<sup>21</sup> who claimed that an agitation of the autonomous nervous system, vegetative Erschütterung, is required before eosinophils appear in the peripheral circulation. E. von Neusser<sup>41</sup> had described eosinophilia following pilocarpine injection as early as 1892, Bertelli, Falta and Schweeger<sup>42</sup> demonstrated the effect of epinephrine (decrease in eosinophils) as well as that of pilocarpine and choline (increase in eosinophils), and attributed the results to action of the drugs on sympathetic and parasympathetic nerves respectively. Camp<sup>43</sup> found, however, that both parasympathetic and sympathetic stimulation raised the number of eosinophils in rabbits which makes the existence of a specific neural regulation rather unlikely.

Hajos<sup>21</sup> had concluded that the injection of foreign protein stimulates the formation of eosinophils in the bone marrow, but that an autonomic shock would force their release into the peripheral circulation. We have always felt that this concept of shock was too vague to support his theory convincingly. In order to test its validity we have grouped the experimental animals which survived the reinjection of the homologous antigen according to severity of shock symptoms. The groups were labeled as follows:

- 1 Severe shock followed by convulsions, collapse and coma ++++
- 2 Sneezing, marked dyspnea, urination and defecation ++
- 3 Chattering teeth, ruffled fur, excitement without respiratory symptoms +
- 4 and 5 Very slight, indefinite, or no symptoms  $\pm$  or 0

The results are found in table 3. In addition to our own findings, we have re-examined the figures published by Weinberg and Seguin, they list the percentage of eosinophils observed in the blood of guinea pigs sensitized with horse serum twelve to twenty-four hours after subcutaneous or intraperitoneal reinjection. Table 3a lists those guinea pigs which had no eosinophils prior to reinjection and are, therefore, comparable to our own, the symptoms were "marked" but no description in detail was given, and we have assumed that they correspond roughly

to our second, ++, group Table 3b lists those of Weinberg and Seguin's<sup>17</sup> animals which had eosinophils ranging from 4 to 17.6 per cent in the peripheral blood

prior to reinjection of horse serum. We have eliminated from our experiments animals which showed an eosinophilia prior to the "shocking" injection because the introduction of another variable factor would further complicate the already

difficult interpretation. In this instance, however, table 3b illustrates well the point in question of the 12 animals listed, 5 had marked symptoms of shock, 7 had none, the fact that only the intraperitoneal, not the subcutaneous, reinjection produced symptoms is of course a phenomenon with which investigators have long since become familiar.

*Results and conclusions.* The tables are self-explanatory and the conclusions are evident. We have been unable to demonstrate any correlation between intensity of shock symptoms and appearance of eosinophils in the peripheral circulation of guinea pigs sensitized and reinjected with horse serum. Our findings compare well with those established by previous authors in experiments which were conducted for different reasons, but employed a technic comparable to ours. They are also in accord with the findings summarized in table 1, where reinjection of hapamine produced a more pronounced eosinophilia in sensitized guinea pigs than ovalbumin, although the anaphylactic symptoms caused by reintroduction of hapamine were much less severe than those which followed the reinjection of ovalbumin.

#### VI. RESPONSE OF NONSENSITIZED AND SENSITIZED GUINEA PIGS TO INJECTION OF SUBSTANCES LIBERATED DURING ANTIGEN-ANTIBODY REACTION HISTAMINE PHOSPHATE, HEPARIN, ADENOSINE

*Experimental problem.* It had been recognized early that while homologous antigen, protein, is instrumental in the course of events which result in peripheral eosinophilia, it is not its direct cause. Schlecht<sup>26</sup> had examined the ability to produce eosinophilia of a considerable number of substances including leucine, alanine, phenylalanine, glycocoll, asparagine, and also sugar, starch and olive oil. All of these failed to produce an eosinophilic response. In view of the complexity of the literature on the subject, it seems necessary to point out that the chemicals which have been tested fall into two categories: those which act, and those which fail to act on vasomotor regulatory mechanisms. It is important to distinguish clearly between the two groups, a considerable portion of described changes might be attributed to a shift in distribution of the corpuscular elements of the blood. Dobreff, Doitschneff and Marinoff<sup>27</sup> have coined the term "Verteilungsleukocytose" for this phenomenon, and—to name a practical application—we suspect that Vaughan's<sup>28</sup> so-called leukopenic index might be explained on a similar basis. Drugs which stimulate or inhibit autonomic nerves, belong to the first group, e.g., epinephrine, atropine, physostigmine, acetylcholine, histamine, substances like sugar or cysteine belong to the other.

The distinction which we have just outlined is important for analysis of factors which participate in development of peripheral eosinophilia. It is possible that the eosinophilic response is controlled by vascular mechanisms, e.g., the afferent and efferent circulation of the bone marrow. Part of the experimental evidence points in this direction. Yet, there are other possibilities to be considered. It is conceivable that the eosinophilic response is due to chemical action on a specific enzyme system, vascular factors might, secondarily, control its intensity. The anaphylactic reaction is complex and involves a variety of biologic changes, such as the contraction of smooth muscles in shock tissues, the decreased coagulability of the

blood, the eosinophilic response Dragstedt<sup>16</sup> has concluded that separate substances are responsible for at least two of these manifestations. The evidence must be considered conclusive that a tissue liberation of histamine, of heparin, and possibly of choline occurs during the anaphylactic reaction in various animals. In the dog the liberation of heparin can completely account for the incoagulability of the blood and there is no reason to doubt that it may be found in other animals. Accordingly, the eosinophilic response again might be caused by a different compound which is not yet defined. It is possible that the distinction which we have suggested will facilitate its eventual identification.

The compounds mentioned by Dragstedt appear subsequently to the antigen antibody reaction. Since most of the substances occur under physiologic conditions in the experimental animal, pathologic changes will not result unless the amount injected exceeds the threshold of physiologic balance. We are unable to predict this threshold with regard to the eosinophilic response, accordingly, conclusions must be restricted to the route and the amount used in each experiment.

As far as we have been able to ascertain, no previous studies have been made of the effect on eosinophilia of adenosine and heparin. There is evidence that either might be released during anaphylactic reactions (Rocha e Silver<sup>17</sup>). Adenosine has a rather weak dilating effect on peripheral arterioles, but administered subcutaneously, [it] causes a migration of leukocytes to the site of injection, an effect which is not produced by histamine (Best and Taylor<sup>18</sup>).

Experimental studies by Campbell<sup>24</sup> demonstrated that guinea pigs which were given 0.5 mg. of histamine, three times a day for three consecutive days, showed no increase in the percentage of eosinophils during five days following the first injection. He found, however, that guinea pigs sensitized and reinjected with ascari keratin responded with a more marked increase in eosinophils when the reinjection of the antigen was followed by a series of histamine injections as previously described. The same effect could be obtained, however, if acetylcholine and cysteine, instead of histamine, were used. It is difficult, therefore, to interpret Campbell's findings. He used substances of different biologic activity and we cannot think of any common denominator. The use of antihistamine drugs in our experiments made it possible to inject an amount of histamine which was comparable to the level of histamine or histamine-like substances liberated during anaphylactic reactions, an amount which would be fatal without this protection, Campbell, in his experiments administered histamine intraperitoneally and did not describe any symptoms of shock such as would have to be expected if similar doses were given intracardially.

If nonantigenic compounds fail to call forth an eosinophilic response, the negative results might be due to the ineffectiveness of the given chemical agent, or to the fact that the injected animal was one of those incapable of producing eosinophilia no matter what the stimulus. We will have to rule out the latter possibility by reinjection of the specific antigen subsequent to the injection of the compound under investigation. Exceptions to this rule would be permissible only if it were possible to obtain a strain of guinea pigs which would afford, under standard experimental conditions, a uniform eosinophilic response. We have

discussed the problem with Dr D H Campbell, whose work seemed to indicate that his experimental animals responded more homogeneously than ours to sensitization and reinjection with a variety of antigens Dr Campbell was kind enough to supply us, for breeding purposes, with several animals from his strain which has been inbred for more than five years We intend to study their response as soon as a sufficient number of animals are available

*Experimental procedure* Guinea pigs (32) were sensitized with horse serum in accordance with the technic outlined in Section II Twenty-one days after the

TABLE 4.—Percentage of eosinophils in the peripheral blood of horse serum sensitive guinea pigs before, three hours and twenty hours after intracardial injection of adenosine, heparin and histamine phosphate respectively Percentage of eosinophils in the peripheral blood of the same animals before three hours and twenty hours after intracardial reinjection of horse serum seventy-two hours later

sensitizing injection, they were divided into three groups The first group (8) was injected with adenosine, 1 mg in 0.5 cc of distilled water, intracardially The injection of adenosine was followed seventy-two hours later by the intracardial reinjection of 0.75 cc of horse serum The second group (8) was injected with heparin, 1 mg in 0.5 cc of distilled water intracardially, the injection of heparin was followed seventy-two hours later by the intracardial injection of horse serum as described before The third group (16) was injected with histamine phosphate 0.5 mg/Kg in 0.5 cc of distilled water intracardially, 1 mg of this solution represents 0.36 mg histamine base The injection of histamine phosphate was followed

seventy-two hours later by the reinjection of 0.75 cc of horse serum intracardially as described before. At the same time, a group of nonsensitized guinea pigs (12) were given histamine phosphate, 0.5 mg/Kg in distilled water, intracardially.

Differential counts were taken before and three hours and twenty hours after each intracardial injection. The animals were given benadryl, 5 mg/Kg in aqueous solution, intraperitoneally, thirty minutes prior to the injection of histamine phosphate and horse serum, adenosine and heparin were injected without protection. Benadryl was selected as the antihistamine drug for this series of experiments, because we had previously shown that, *per se*, it failed to increase the percentage of eosinophils in the sensitized guinea pig.

**Results.** The results of the injections of adenosine, heparin and histamine followed by the reinjection of horse serum are listed in table 4. Adenosine, in the amount injected did not produce an increase in eosinophils, the increase observed after the injection of heparin is not significant enough to warrant conclusions, it might be caused, for instance, by a minute amount of impurities which adhere even to highly purified preparations.

A considerable number of animals injected with histamine died immediately after or during the first twelve hours following the injection. There was, however, no apparent difference in tolerance between the non-sensitized and sensitized group. The non-sensitized animals had a differential count of 0, 0, 1, 2, 3 and 6 per cent eosinophils, respectively, twenty hours after the intracardial injection of histamine phosphate. The percentage of eosinophils in the sensitized group range from 0 to 17 per cent, 6 of the 8 animals, however, which are included in this group, had an eosinophil count of 5 per cent or more.

The reinjection of horse serum makes it evident that animals No. 417 and No. 449 must be eliminated from the series for both failed to respond to the subsequent reinjection of the specific antigen. Animal No. 361 has been included in order to emphasize the fact that the response of the guinea pig to any given substance is obscured if an eosinophilia is present prior to the experiment, this is true even if the response to subsequent reinjection of the specific antigen is satisfactory.

Table 4 also lists the differential eosinophil count obtained three hours after intracardial injection. We are unable as yet to explain the variation in speed with which the maximum percentage of eosinophils is reached. Animals No. 359 and No. 362, for instance, had 3 per cent eosinophils after three hours, but the former showed 17 per cent, the latter only 5 per cent after twenty hours. Similarly, the return to the pre-experimental level varies considerably. The behavior of the eosinophils in animals which showed an eosinophilia prior to the reinjection of the specific antigen, presents another interesting aspect of the same question. We have listed, in table 5, two groups of guinea pigs sensitized and reinjected with horse serum. The first group had not more than 1 per cent, the second group from 2 to 7 per cent eosinophils before the shocking injection of horse serum was given. A comparison of the percentage of eosinophils observed in each group three hours and twenty hours after reinjection, makes us suspect that a balance develops between an initial disappearance and a secondary reappearance of eosinophils in the

blood stream Differential counts at short intervals might provide a definite answer, they would extend, however, our study beyond its present scope

*Conclusions* The observation that histamine per se is able to produce an increase in eosinophils in the blood of sensitized guinea pigs, might explain Campbell's findings that it enhances the eosinophilic response which follows the reinjection of homologous antigen We hesitate on the other hand to draw any more far-reaching conclusions as to the underlying mechanism, since Campbell reports even a larger increase by the use, in a corresponding technic, of acetylcholine and cysteine

## VII CORRELATION OF EOSINOPHILS IN BONE MARROW, PERIPHERAL CIRCULATION AND SHOCK TISSUE

*Experimental problem* It had been recognized and stated by early investigators that any attempt to understand the mechanism of peripheral eosinophilia requires the simultaneous study of bone marrow, peripheral circulation and shock tissue Curiously enough, no accord has been reached about the interpretation of findings Weinberg and Seguin,<sup>17</sup> for instance, found in a study of eosinophils in the blood and lungs of guinea pigs that 4 out of 10 animals sensitized but not reinjected with horse serum as well as 9 out of 22 animals sensitized and reinjected with horse serum had eosinophils in their lungs provided they had a high eosinophil count in their blood They concluded that the presence of eosinophils in the lungs had no relation to anaphylaxis and termed the phenomenon chronic spontaneous eosinophilia

Hajos,<sup>21</sup> on the other hand, using the same species and the same antigen, based his conclusions on the examination of bone marrow, peripheral blood count and lungs of guinea pigs sensitive to horse serum prior to reinjection and from eight to forty-eight hours after reintroduction of the specific antigen by intramuscular injection or by inhalation He found that of the three groups examined only those which were re-exposed to the antigen by inhalation showed a pulmonary eosinophilia Homma,<sup>18</sup> who used white rats injected with parasites and parasitic material, felt confident that he had established a direct relationship between eosinophils in bone marrow, blood and shock tissue He maintained that eosinophils increase in the bone marrow during sensitization and, furthermore, that he had been able to correlate their subsequent decrease in the bone marrow with their increase in the peripheral circulation and their final decrease in the peripheral circulation with their increase in the shock tissue The cycle thus established would confirm Ehrlich's concept of the origin and distribution of eosinophils Unfortunately, his paper contains neither figures nor a description of his methods, and the Japanese journal to which he refers for the details of his experimental procedure is not available to us It is therefore impossible to reproduce his experiments For this and other reasons mentioned earlier, we decided to study bone marrow and shock tissues of a series of guinea pigs which were sensitized and reinjected with horse serum by the standard procedure employed throughout our investigation

The study of bone marrow presented us with a number of technical problems. Comparative studies convinced us that of the three available methods, marrow puncture, touch preparation of marrow, and marrow section, the last gave the most consistent results. The number of eosinophils within the area of a grid was the technic adopted \*

FIG. 1 Eosinophils accumulated in the periphery of an intrapulmonary lymph node of a guinea pig sensitized and reinjected with horse serum twenty hours after reinjection. Hematoxylin azure-eosin. Magnification  $1 \times 400$

The examination of shock tissues does not offer any particular difficulties. The lungs which represent the essential shock tissue in the guinea pig were classified into six groups according to the number of eosinophils observed

- no eosinophils o
- few eosinophils (one or two per h p f) +
- moderate eosinophilia ++
- marked eosinophilia +++
- massive eosinophilia ++++

This corresponds roughly to the classification used by Weinberg and Seguin<sup>17</sup>

\* We are indebted to Dr. L. R. Lamarca for his suggestions and his help in identifying the preparations.

The eosinophils are seen to accumulate in the perivascular and peribronchial connective tissue. They are prevalent in septal tissue and bronchial walls and are imbedded in mucus in the lumen of the bronchi. As a rule, a large number surround the intrapulmonary lymphatic tissue which occurs normally in guinea pigs, and while a few are observed in lymphatic channels, the major portion is found in the periphery of the lymphnodes (fig 1), a relationship which had been described by Opie<sup>15</sup> more than forty years ago.

*Experimental procedure* Guinea pigs (18) were sensitized to horse serum by the method previously described. Twenty-one days later, they were divided into three groups of 6 animals each. One group was given 0.75 horse serum intracardially without protection, the second group received benadryl, 5 mg/Kg in aqueous solution, the third group SY 18, 1.5 mg/Kg in aqueous solution intraperitoneally, thirty minutes prior to the intracardial reinjection of horse serum. Three of the unprotected animals and two of the animals protected with SY 18 died from the result of immediate or delayed anaphylactic reactions.

Another series of guinea pigs (6) was sensitized by intraperitoneal injection of 0.75 cc of 1 per cent ovomucin in aqueous solution. Twenty-one days later, the guinea pigs were divided into three groups of two animals each. One group was given 0.75 cc of a 1 per cent aqueous solution of ovomucin intracardially without protection, the second group received benadryl, 5 mg/Kg in aqueous solution, the third group SY 18, 1.5 mg/Kg in aqueous solution, thirty minutes prior to the reinjection of ovomucin. One of the unprotected animals died from the results of immediate anaphylactic shock.

None of the animals had more than 1 per cent eosinophils prior to reinjection. Twenty hours after the intracardial reinjection, differential counts were obtained in all the animals, and in four nonsensitized guinea pigs. After the counts had been taken, the animals were sacrificed. The first animals were sacrificed by fracturing their necks. In view of the marked extravasation of blood which results from violent death, this procedure was abandoned and the majority of the animals were sacrificed by intracardial injection of nembutal in aqueous solution. Immediately after death, postmortem examinations were performed, specimens were removed of lungs and of any organ which showed gross pathologic changes. One femur was carefully opened, the bone marrow penciled out in toto. The specimens were fixed in Zenker-Formol, freshly prepared. They were imbedded in paraffin and stained with hematoxylin-azure-eosin. This stain permits a satisfactory identification of eosinophils in all preparations. A grid inserted into the ocular of the microscope was used for the counting of eosinophils in the bone marrow. The figures thus obtained are relative figures and not comparable with those quoted by other authors.

*Results* The correlation of eosinophils in bone marrow, peripheral circulation and lungs is summarized in table 6.

1. Bone marrow. Eosinophil counts in the bone marrow of non-sensitized guinea pigs varied from 8 to 52 in the area of the grid used during this study, in the bone marrow of guinea pigs sensitized and reinjected with horse serum, from 7 to 62 in the bone marrow of guinea pigs sensitized and reinjected with ovomucin, from

TABLE 5—Percentage of eosinophils (before, three hours and twenty hours after reinjection) in guinea pigs sensitized and re injected with horse serum

The first group had 1% or less, the second group from 2% to 7% eosinophils prior to reinjection

18 to 83. The average of the animals reinjected with horse serum is slightly higher, and of those reinjected with ovomucin considerably higher, than the average of nonsensitized controls. We believe that the difference between nonsensitized and sensitized animals is likely to be more pronounced before rather than after the reinjection which causes a redistribution of eosinophils. Two animals must be classified as experimental failures: guinea pig No. 325 failed to respond to sensitization and reinjection with horse serum, it showed for unexplained reasons

FIG. 2. Eosinophilia in the lung of a guinea pig sensitized and reinjected with horse serum, twenty hours after reinjection. Benadryl, 5 mg/Kg intraperitoneally thirty minutes prior to reinjection. Hematoxylin azure-eosin.

neither anaphylactic symptoms nor tissue reactions. Guinea pig No. 335 is listed without its bone marrow count since a technical mishap made the specimen unfit for interpretation.

The variation between the eosinophil counts in the bone marrow of individual guinea pigs is so marked that the examination of the bone marrow does not permit any conclusion as to whether it has been obtained from a non-sensitized animal or from an animal which has been sensitized and reinjected with the specific antigen. We have not been able to establish any correlation between the number of eosino-

phils in bone marrow and peripheral blood. Five guinea pigs which had peripheral counts of 10, 12, 16, 17 and 19 per cent respectively, had, in the corresponding order, bone marrow counts of 17, 22, 29, 15 and 62 eosinophils in the grid area.

2. **Lungs** Of the nonsensitized controls, eosinophils were absent in 2 specimens, one showed a few eosinophils, one a moderate number and none of the controls had eosinophils in their peripheral blood at the time of death. Of the guinea pigs sensitized and reinjected with horse serum, 3 failed to show eosinophils in the lungs, 4 showed a few eosinophils, 4 had a moderate, 1 a marked and 1 a massive eosinophilia. Of the guinea pigs sensitized and reinjected with ovomucin, 2 failed to show eosinophils, 2 showed a few eosinophils, 1 had a marked eosinophilia. Of the 5 animals which showed a moderate eosinophilia in their lungs, 3 had a peripheral eosinophil count of 5 per cent or more, the animals (3) which had a marked or massive pulmonary eosinophilia, had peripheral eosinophil counts of 12, 16 and 17 per cent. With the exception of the control (guinea pig No. 416), the animals which displayed a moderate pulmonary eosinophilia, had been protected with benadryl, those which showed a marked or massive eosinophilia, with SY 18. On the other hand, eosinophils were absent in one of the animals treated with benadryl, one of the animals treated with SY 18, a few eosinophils were seen in the remaining animals of either group. Anti-histamine drugs did not abolish the eosinophilic response in the lungs of guinea pigs sensitized and reinjected with antigen. Figure 2 shows the histologic section of the lung of guinea pig No. 332 protected by benadryl.

A definite correlation appears to exist between peripheral eosinophilia and shock tissue. All of the animals which had more than 10 per cent eosinophils in the peripheral blood, showed a moderate, marked, or massive number of eosinophils in their lungs.

**Discussion** 1. Bone marrow Hajos<sup>21</sup> who tried to correlate eosinophilia in bone marrow, blood and lungs, found percentages of 1.3 per cent and 1.5 per cent of cells with eosinophilic granules—myelocytes, myeloblasts and mature cells—in the bone marrow of normal guinea pigs. He counted a total of 1000 bone marrow cells—a technic comparable to our own. Accepting these figures as a base line, he proceeded to examine the bone marrow of guinea pigs sensitized to horse serum. The percentage of eosinophils increased to a maximum of 9 per cent, while the peripheral eosinophil count failed to rise. Intramuscular reinjection of the specific antigen decreased the percentage of eosinophils slightly, inhalation of the specific antigen considerably. The differential count of the bone marrow, eight to twenty-four hours after exposure of the sensitized guinea pig to nebulized horse serum, ranged from 1 per cent to 3 per cent. At the time of the decrease in eosinophils of the bone marrow, a slight increase was noted in the peripheral blood, it did not exceed, however, 4 per cent in the latter group. We have been unable to confirm the existence of a normal eosinophil count in the bone marrow of guinea pigs. The pronounced variation, in our opinion, is explained by the actual difference in the number of eosinophils present in the bone marrow of each individual animal, but is enhanced by the characteristics of distribution of eosinophilic cells within the same bone marrow. Figure 3, a bone marrow section of guinea pig No. 411,

illustrates the irregularity of the pattern which becomes even more significant when the percentage of eosinophils is low. The latter consideration is of minor importance. Examination of several sections and increase of the total number of cells counted might establish a valid average. While it might thus be possible to observe increase or decrease of cells with eosinophilic granulation in the same animal, we do not believe that changes in the percentage of eosinophils in the bone marrow of different guinea pigs are comparable.

FIG. 3 Eosinophils in the bone marrow of a non-sensitized guinea pig. Hematoxylin azure-eosin. Magnification  $1 \times 400$ .

2. Lungs. The study of eosinophils in shock tissues has assumed renewed importance, since Halpern<sup>49</sup> reported that the injection of antihistamine drugs derived from thiodiphenylamine prevented the eosinophilia usually found in the lungs of guinea pigs twenty-four hours after the anaphylactic reaction. Halpern, in his experiments, used sheep serum as antigen, the sensitizing dose was given intraperitoneally in two portions, three days apart, the shocking dose, fifteen to twenty-one days later into the jugular vein. He states that this technic causes fatal shock in 100 per cent of unprotected animals. Its anaphylactic antigenicity appears to be superior to the horse serum used in our experiments, we have no information about the peripheral eosinophilic response in the animals thus sensitized. If the series

of antihistamine drugs studied by Halpern prevents the development of an eosinophilia in shock tissues, while the type of preparations which we have used either fails to influence or even increases the number of eosinophils present, the difference thus established should provide a clue of fundamental significance

3 Correlations The concept of chronic spontaneous eosinophilia which we have mentioned in the beginning of this section has been developed by Weinberg and Seguin<sup>17</sup> as the result of comparative studies of blood and lungs in sensitized guinea pigs before and after reinjection of the specific antigen. We have no cause to doubt the validity of their findings, but we are certain that the observations upon which the concept is based require re-evaluation, because a large number of the experimental animals had a high peripheral eosinophil count prior to reinjection. The importance of this distinction becomes evident, if we analyse the factors which might influence the number of eosinophils in blood and shock tissue. We have reason to assume that a specific stimulus such as originates during the antigen antibody reaction is necessary to produce a peripheral eosinophilia. Opie,<sup>18</sup> Weinberg and Seguin,<sup>17</sup> and recently Ingraham and Wortman<sup>19</sup> have demonstrated beyond doubt, however, that the chemotactic behavior of eosinophils equals that of neutrophils, that they are, moreover, phagocytic in vitro and in vivo. Accordingly, if they are once present in the blood stream, a variety of pathological changes might account for their presence in various tissues, this is one of the considerations which has caused us to restrict our studies to guinea pigs which had no peripheral eosinophilia prior to reinjection of the specific antigen.

The second factor which might influence the distribution of eosinophils in blood and shock tissue is even more pertinent because it applies to our own experiments in which the antigen antibody reaction was the immediate and undisputable cause for appearance of eosinophils in the circulation. Our studies seem to confirm Weinberg and Seguin's observations which correlate peripheral and pulmonary eosinophilia. Yet it has to be pointed out that this apparent correlation might be seriously distorted. Gerlach<sup>20</sup> in his classic experiments had emphasized the importance of factors which determine where the antigen antibody reaction is localized. The lungs represent only one of the shock tissues of the guinea pig; the entire gastrointestinal tract, bladder, uterus, and skin are bound to participate in antigen antibody reactions and to influence the distribution of eosinophils. It is quite likely, as a matter of fact, that the total number of eosinophils present in shock tissues, other than lungs, might be considerably larger than the pulmonary fraction. Figure 4 represents a typical example: a section of the stomach of guinea pig No. 323 which was sensitized and reinjected with horse serum. The guinea pig, although not protected by antihistamine drugs, did not exhibit anaphylactic symptoms, it was sacrificed twenty hours after reinjection. It had a peripheral eosinophil count of 7 per cent at the time of its death. Only few eosinophils are seen in its lungs, the stomach, on the other hand, shows marked edema and a massive eosinophilia. It is obvious that in the representative case of the animal which we have just described, a comparative study which disregards the gastric reaction would be of doubtful value. We were impressed by the apparent affinity of eosinophils to the connective tissue of the specimens which we have examined.

It is possible that the eosinophilic response might require the interaction of the antigen with the tissue during the antigen-antibody reaction with a connective tissue component in the organs. We have no concept of the possible manner in which the connective tissue might participate in the

FIG. 4. Eosinophils in the lamina propria of the stomach of a guinea pig, sensitized and re injected with horse serum twenty hours after reinjection. Hematoxylin azure-eosin. Magnification  $1 \times 100$ .

process of sensitization, but we suspect that further studies of the function of eosinophils will also uncover a specific function of the connective tissue which has, so far, escaped our attention.

While we feel that the results of our studies on correlation are of interest with regard to the action of antihistamine drugs, we are also aware of the fact that the actual problem of the mechanism which correlates the presence of eosinophils in blood and lungs has not been solved. It is not possible to decide by static in-

vestigations such as ours and those of previous workers whether the increase of eosinophils in the blood is the cause or the result of the eosinophilia observed in shock tissue. It might be necessary to study the eosinophilic response in shock organs which are isolated *in vivo* and permit the continuous determination of the percentage of eosinophils in the arterial and venous circulation with which they are supplied. In humans, the investigation of the eosinophilic response in shock tissues has been confined to the skin.

Kline, Cohen and Rudolph<sup>52</sup> found a marked eosinophilic infiltration in the skin of allergic individuals, twenty to twenty five minutes after injection of either histamine or specific antigen. The initial count of 50 per cent decreased to about 10 per cent after three hours. Nonallergic persons failed to exhibit this transitory local eosinophilia, the injection of histamine caused only a slight inflammatory reaction.

Jadassohn<sup>53</sup> on the other hand described local eosinophilia in the human skin after mechanical irritation injection of morphine, atropine or pilocarpine even in the absence of blood eosinophilia.

Knott and Pearson<sup>54</sup> demonstrated in similar studies that the site of a positive skin test in allergic individuals contains twenty minutes after injection of the antigen approximately twice as many eosinophils as the peripheral blood, the site of a negative skin test in allergic individuals as well as in normal controls, a number which equals the peripheral count. The injection of histamine causes a local eosinophilia in the wheals formed in either nonallergic or allergic individuals. It is twice as high as the peripheral count in the former two and one-half times as high in the latter.

It must be assumed that the discrepancies in the findings of the three authors are due to a lack of uniformity in those factors which determine genesis and extent of local eosinophilia, e.g., in type and degree of individual sensitivity. We hope that the controlled conditions of the animal experiment will permit us to arrive at conclusions which clarify the open question about the agents responsible for the presence of eosinophils in shock tissues.

### VIII. CONCLUSIONS

Our results appear to have clarified a number of questions which have obscured the investigation of the eosinophilic response. It has been shown that discrepancies found in the literature are largely due to variations inherent in the nature of the antigen, its route of administration and variations in the responsiveness of the experimental animal. We have standardized our experimental procedure to eliminate as many variables as possible. Shock *per se* does not seem to account for the eosinophilia which develops subsequent to the reinjection of the specific antigen in sensitized guinea pigs. The eosinophilic response, unlike the anaphylactic reaction, is not abolished by the antihistamine drugs which we have used. Observation of eosinophils in the blood and tissue of animals thus protected suggest that there might be important differences between the various types of antihistamine drugs which are now available. We have, finally, analyzed the possible correlation between eosinophilia in bone marrow, peripheral circulation and shock tissue. Although such correlation has been found to exist in several instances, we have also come to realize the limitations which prohibit far reaching conclusions.

It might be permissible to discuss briefly possible avenues of future approach. In view of the fact that eosinophils appear subsequent to sensitization and reinjection of antigen, several investigators have attempted to relate the function of the

eosinophil to the antigen antibody reaction and to reproduce its assumed action *in vitro*. All these experiments have remained inconclusive.

Weinberg and Seguin<sup>17</sup> for instance sensitized guinea pigs with repeated intraperitoneal injections of hydatid fluid and obtained a peritoneal exudate rich in eosinophils. The cells were washed, counted, resuspended in a measured amount of hydatid fluid and incubated. Complement fixation tests on the fluid before and after incubation revealed a loss of antigen proportional to the number of eosinophils in the exudate. The experimental technique used by these authors, however, permits interpretations other than those proffered; we hesitate to accept their conclusion that the antigen has been absorbed by the eosinophils which they suggest might produce specific antibodies after absorption.

Three recent publications refer to *in vitro* experiments on the function of eosinophils in the mechanism of antigen antibody reactions. Ringo<sup>20</sup> writes: "Olson's recent studies of the eosinophils in immune reactions indicate that a specific sensitizing product is formed between eosinophilic leukocyte granules and complex proteins." Osgood<sup>21</sup> with Perlman studied the development of eosinophils in bone marrow cultures. Eosinophils formed when the specific allergen was added to cultures of the marrow of allergic patients. They did not develop in cultures of bone marrow of nonallergic individuals which had been sensitized by addition of a small amount of allergic serum. Histamine did not produce eosinophilia in either allergic or nonallergic cultures. Kirk<sup>22</sup> finally reports: "Dr. Houghton in tissue cultures of cells from normal adults plus the serum of sensitive individuals produced an increasing number of developing eosinophils; likewise the juvenile and adult eosinophilic cells lived longer." In an attempt to secure additional details we have communicated with each of the authors, unfortunately—in part due to circumstances beyond control—none has completed the work beyond this suggestive stage.

While it is conceivable that *in vitro* studies might result in the sudden discovery of the function of the eosinophil, *in vivo* experiments will accomplish the same objective by a steady process of elimination and change. We believe as Campbell<sup>24</sup> does that whatever the function of the eosinophil may be it is the same under all conditions. Of several theories, however, which have been advanced to explain the presence of eosinophils in blood and shock tissues after antigen antibody reactions, none has been confirmed.

## IX. SUMMARY

1. The eosinophilic response of the guinea pig sensitized and reinjected with the specific antigen varies with the nature of the antigen used, but also with the individual guinea pig in any group sensitized and reinjected with the same antigen.
2. Certain antihistamine drugs which abolish anaphylactic symptoms, do not abolish the eosinophilic response.
3. The severity of anaphylactic shock symptoms has no influence on the eosinophilic response.
4. Histamine phosphate has no effect on the eosinophil count of nonsensitized guinea pigs; protected by benadryl, it causes a distinct eosinophilic response in sensitized animals.
5. Heparin—in the dose injected—produced only an insignificant rise in the peripheral eosinophil count of sensitized guinea pigs; adenosine had no effect.
6. Attempts were made to correlate the eosinophilic response in bone marrow, blood and shock tissue of guinea pigs sensitized and reinjected with a specific antigen. The variation within a wide range of the number of eosinophils in the bone marrow of nonsensitized and of sensitized, reinjected guinea pigs is emphasized. A definite correlation seems to exist between the presence of a large number of

eosinophils in blood and lungs, it is shown, however, that this observation permits only limited conclusions

7 The factors which account for discrepancies in the interpretation of the eosinophilic response, e.g., nature of antigen, route of administration and characteristics of species, are analyzed

8 The significance of the findings is reviewed in the light of previous work

#### ACKNOWLEDGMENT

We wish to express our appreciation to Miss Alice Sprenger for her patient and efficient technical assistance

## INTRODUCTION

IN 1945, Nolf<sup>1</sup> described a serum constituent, distinct from thrombin, which was capable of furthering coagulation. More recently, Ware et al.<sup>2-4</sup> reported a substance, designated serum Ac globulin, which activates the conversion of prothrombin to thrombin by thromboplastin. Independently, Owren<sup>5</sup> discovered a new clotting factor, Factor VI, which arises during coagulation, speeds the evolution of thrombin, and catalyzes its own formation. These observations are of fundamental importance in our knowledge of blood clotting since they help explain the autocatalytic process underlying the evolution of thrombin.

We observed that the admixture of serum to plasma accelerates the conversion of prothrombin to thrombin following the addition of thromboplastin plus calcium. This report presents data regarding some physiologic and biochemical properties of the agent (serum prothrombin conversion accelerator) responsible for this effect, together with a method for its estimation. A study of its role in blood coagulation and in the pathogenesis of certain hemorrhagic disorders is reserved for subsequent communications.<sup>6</sup>

## METHODS

*General Considerations.* The determination of plasma prothrombin by the one stage technic<sup>7</sup> has two disadvantages: (a) the prothrombin time is considerably influenced by both the concentration of prothrombin and certain nonprothrombin substances<sup>8-12</sup>, (b) above 50 per cent (of normal) prothrombin concentration the decrement in prothrombin time with significant increment in prothrombin is so small as to be almost within the limits of error of measurement. To obviate these disadvantages, oxalated plasma was suitably diluted with normal plasma rendered essentially free of prothrombin by prior adsorption with barium sulfate according to the technique of Rosenfield and Tuft.<sup>13</sup> Plasma so treated† contains adequate amounts of nonprothrombin substances which affect the prothrombin time.<sup>14, 15</sup>

This technic is applicable also to the determination of the prothrombin activity of serum. Since however serum contains a factor which accelerates the conversion of prothrombin to thrombin, it is a priori evident that the prothrombin times may reflect the concentration of both prothrombin and the accelerator. It would therefore be incorrect to derive serum prothrombin concentrations from prothrombin times. Accordingly we have interpreted the latter in terms of prothrombin activities.

*Plasma Prothrombin.* Plasma prothrombin was determined by the method of Rosenfield and Tuft.<sup>13</sup> 0.1 cc. of oxalated plasma (1 volume of 0.1 M sodium oxalate solution to 9 volumes of blood) was mixed

† Aided by a fellowship from the Rothschild Hadassah University Hospital, Jerusalem.

‡ Referred to as BaSO<sub>4</sub> plasma throughout this paper.

with 0.9 cc of fresh oxalated  $\text{BaSO}_4$  plasma. The latter was prepared in the following manner: barium sulfate (C.P.) was added to plasma (100 mg per cc). The mixture was shaken, incubated at 37°C for ten minutes, with repeated shaking and centrifuged at 3000 r.p.m. for thirty minutes. The supernatant was kept at 0-4°C and was used within two hours after its preparation as the diluent for the test plasma.

Thromboplastin extracts were prepared every two weeks from commercial (Difco) thromboplastin. 0.1 cc aliquots were pipetted into prothrombin time tubes which were then stored at -23°C. Under such conditions the potency remains unchanged for at least two weeks.<sup>10</sup> Immediately before use the tubes containing the frozen thromboplastin were thawed for 10 minutes at 37°C, 0.1 cc of the plasma mixture was then added followed by 0.1 cc of 0.02 M  $\text{CaCl}_2$  solution and the time of clotting observed while the mixture was constantly stirred with a wire loop. All determinations were done at least in duplicate.

A curve relating prothrombin concentration with prothrombin time was derived from determinations on normal plasma serially diluted with increasing amounts of  $\text{BaSO}_4$  plasma. Plasma prothrombin activity was computed from this curve after correction for dilution.

*Serum Prothrombin Activity.* Serum prothrombin activity was determined in the same manner. Unless otherwise indicated, venous blood was allowed to clot spontaneously at room temperature. After standing for one hour the clot was spun and the serum separated. To 9 volumes of serum was added one volume of 0.1 M sodium oxalate solution; the mixture was incubated for 30 minutes at 37°C, and thereafter kept in the refrigerator until used (within three hours). Since the prothrombin activity of normal serum is low, the proportion of serum to  $\text{BaSO}_4$  plasma in the mixture to be tested was 3 to 7. Such proportions assure adequate amounts of nonprothrombin factors which affect the prothrombin time.<sup>11</sup>

*Serum Prothrombin Conversion Accelerator (SPCA).* 0.05 cc of oxalated plasma were mixed with 0.9 cc of  $\text{BaSO}_4$  plasma, 0.05 cc of oxalated serum were then added and the prothrombin time determined on 0.1 cc of the mixture. The SPCA was calculated by subtracting the algebraic sum of the individual prothrombin activities of the serum and plasma components from the observed prothrombin activity of the mixture, the value thus obtained divided by the algebraic sum gives the percentage enhancement of prothrombic activity. For example: Assume the plasma to contain 100 per cent (of normal) prothrombin activity and serum 10 per cent. A mixture of equal volumes of both should show 55 per cent activity. If the observed value is 120 per cent, the SPCA is

$$\frac{120 - 55}{55} \times 100 = 118 \text{ per cent enhancement}$$

### PHYSIOLOGIC PROPERTIES

*Demonstration of SPCA.* The addition of oxalated serum to oxalated plasma diluted with  $\text{BaSO}_4$  plasma shortens the prothrombin time markedly (table 1).

*Accuracy of SPCA Assay.* Aliquots of serum from a blood sample from one subject were mixed with aliquots of plasma and  $\text{BaSO}_4$  plasma obtained from a second subject. The SPCA's of 9 of these aliquot mixtures ranged from 138 to 168 per cent with a mean of 149 (S.D. 8.6). Ten observations made with the same serum as above but mixed this time with plasma and  $\text{BaSO}_4$  plasma from a third individual ranged from 118 to 162 with a mean of 139 (S.D. 12.3). The standard deviation of all 19 observations was 18.7.

*Is SPCA Identical with Thrombin?* The question arises whether SPCA activity is referable to serum thrombin which is demonstrable in serum shortly after coagulation. Incubating serum for one-half hour does not decrease SPCA (table 2), although thrombic activity is inactivated by serum antithrombin. To prove that this serum could inactivate considerable amounts of thrombin, 125 units (Parke Davis, Topical Thrombin) were added to 1.0 cc. A drop of the mixture added immediately to 0.5 cc of plasma resulted in instantaneous clotting. The same mixture, incubated for one-half hour at 37°C, gave no clot in 1 hour when added to plasma, and con

tained less than 1.25 units of thrombin when its coagulating effect was compared with that of a standard thrombin preparation under standard conditions.<sup>5</sup>

The binding of thrombin by serum antithrombin is an equilibrium reaction in which a small amount of thrombin may remain free.<sup>17</sup> Conceivably, SPCA activity may be due to a trace of thrombin which might not otherwise be demonstrable. This was excluded by the following experiment (table 3). Small amounts of

† This experiment was run immediately after the addition of the serum to the plasma barium sulfated plasma mixture in order to obviate spontaneous clotting resulting from thrombin in the serum.

‡ Corrected for dilution with BaSO<sub>4</sub> plasma

thrombin added to plasma-barium sulfated plasma mixtures had a negligible effect on the prothrombin time although the added thrombin induced clotting after a latent period. The addition of serum *which had a large SPCA activity*, on the other hand, did not result in coagulation in the same interval.

*Does SPCA Activity Affect the Reaction between Fibrinogen and Thrombin?* The prothrombin time measures the speed of both prothrombin conversion to thrombin and the reaction of thrombin with fibrinogen. Theoretically, SPCA might act by accelerating the second of these reactions. Mixtures of plasma, serum and BaSO<sub>4</sub>

plasma were prepared in the usual manner and SPCA determined. To 0.4 cc of the mixtures were added 0.4 cc of a veronal sodium chloride buffer (pH 7.38), prepared according to Owren,<sup>5</sup> and 0.2 cc of thrombin solution (Parke-Davis Topical Thrombin) containing 2.5 or 5 units per cc (in Owren's buffer). The data (table 4) show that SPCA does not affect the speed of fibrinogen transformation into fibrin.

† Corrected for dilution with BaSO<sub>4</sub> plasma.

*Quantitative Relationship between SPCA Effect and Plasma-Serum Ratio in Mixture*  
SPCA activity was determined on mixtures in which the concentrations of serum and plasma were varied. With 0.02 to 0.30 cc of plasma were mixed 1.30 cc of BaSO<sub>4</sub> plasma. To each of the mixtures, 0.05 cc of serum were added, the volumes were adjusted to 2.00 cc with physiologic saline, and the prothrombin times measured. In other experiments the plasma was kept constant and the serum was varied, viz. To a mixture of 0.05 cc plasma and 1.30 cc of barium sulfated plasma were added 0.02 to 0.50 cc of serum, and saline to a final volume of 2.00 cc. As the serum concentration increases, the velocity of conversion of plasma prothrombin

to thrombin increases (figs. 1, 3). Maximal SPCA activity is reached when the serum concentration is approximately tenfold that of plasma. The effect of maintaining the serum constant and varying the plasma concentration is shown in figures 2 and 3.

*Is SPCA Activity Due to Thromboplastin?* Very recently, Chargaff<sup>18</sup> reported that thromboplastin is not consumed during blood coagulation. This contradicts the claim of Mertz et al.<sup>19</sup> It has furthermore been shown that platelet extracts can accelerate the prothrombin time of fresh or stored plasma.<sup>20</sup> The possibility that

FIG. 1—ENHANCEMENT OF PLASMA PROTHROMBIN ACTIVITY INDUCED BY ADMIXTURE OF PROGRESSIVELY INCREASING AMOUNTS OF PROTHROMBIN FREE SERUM  $\frac{A}{B} \times 100 = \text{SPCA Activity}$

the clot promoting effect of serum might be due to unconsumed thromboplastin required investigation.

The addition of thromboplastin extracts (0.1 cc. of Difco prepared as for prothrombin determination) to 2.0 cc. of oxalated serum resulted in no enhancement of its SPCA activity. Furthermore, thromboplastin (0.05 cc.) added to a mixture of 0.05 cc. plasma and 0.9 cc. of  $\text{BaSO}_4$  plasma did not alter the prothrombin time. Platelet extracts obtained with saline, distilled  $\text{H}_2\text{O}$  or a solution of saponin also gave negative results.

*Relation Between SPCA and Labile Factor* As plasma is stored, its prothrombin activity decreases although the concentration of prothrombin remains unchanged.<sup>21</sup>

FIG. 2.—PLASMA PROTHROMBIN ACTIVITY IN PLASMA-SERUM  $\text{BaSO}_4$  PLASMA IN WHICH SERUM CONCENTRATION IS FIXED AND PLASMA CONCENTRATION IS VARIED  $\frac{A}{B} \times 100 = \text{SPCA Activity}$

FIG. 3.—EFFECT OF SERUM ON VELOCITY OF PROTHROMBIN CONVERSION TO THROMBIN  $t_p + s$  is the prothrombin time of the plasma serum mixture  $t_p$  is the prothrombin time of the plasma

This is due to deterioration of a labile factor.<sup>8</sup> The addition of prothrombin free fresh plasma to stored plasma restores the prothrombin time to normal. According to Mann et al.<sup>10</sup> and Munro and Munro,<sup>11</sup> serum also can lower the prothrombin time of stored plasma. This has also been confirmed by us. The question whether this restorative ability of serum is referable to its labile factor or to SPCA required elucidation.

When normal human blood is added immediately to thromboplastin extract (9.0 cc blood to 1.0 cc Difco thromboplastin extract), its serum often contains much more SPCA activity than the serum of blood allowed to clot spontaneously.<sup>6</sup> An experiment was done in which a serum, thus prepared, exhibited marked SPCA activity, although its restorative effect on the prothrombin time of stored plasma was negligible (table 5). It should be noted, however, that serum obtained from blood drawn into thromboplastin is not always devoid of labile factor.

TABLE 5—Comparison of SPCA Activity of Serum with its Ability to Reactivate the Prothrombin of Stored Plasma

Oxal serum	Serum prothr activity	SPCA activity on fresh plasma	Restorative effect of serum on stored plasma Prothrombin time	
			Stored plasma	Stored plasma plus serum (1:1)
	%	%	sec	sec

From blood clotted spontaneously				
Fresh	4	121	87	18.4†
Incub 4 hrs at 37°C	<3	100	80	44.2
Kept 26 hrs at room temp	1	75	89	69

\* Oxalated human plasma aged 32 days at 4°C

† This value is comparable to the prothrombin time (17.8 sec) obtained on a 1:1 mixture of this stored plasma with fresh plasma.

Labile factor deteriorates more rapidly at 37°C than at refrigerator temperature.<sup>22, 13</sup> In serum aged at body or at room temperature labile factor deteriorates much more rapidly than SPCA (table 5). Additional experiments on the lability of SPCA and other biochemical properties will be presented later.

*Effect of Serum on the Prothrombin Conversion Rate of Stored Plasma with and without Supplements of Labile Factor.* Oxalated serum from blood drawn into thromboplastin was kept at room temperature for twenty-six hours. It was free of prothrombin and rich in SPCA. A mixture of equal parts of this serum with stored plasma whose prothrombin time was 90 seconds (indicating 12 per cent of normal prothrombin activity) gave a prothrombin time of 116 seconds (indicating 10 per cent prothrombin activity). When, however, the mixture was diluted 1 to 9 with BaSO<sub>4</sub> plasma (rich in labile factor), the prothrombin activity of the serum-plasma mixture was almost twice that of the plasma alone similarly diluted with BaSO<sub>4</sub> plasma (table 6). It appears that SPCA needs, for its activity to become manifest, a factor present in fresh plasma, whole or barium sulfated, and absent in stored plasma.

*SPCA Activity in the Presence of Heparin* Heparin added to serum-plasma mixtures in concentrations capable of lengthening the prothrombin time of plasma alone did not abolish SPCA activity (table 7)

TABLE 6—*SPCA Activity at Low and Normal Concentration of Labile Factor*

### *Biochemical Properties of SPCA*

*Stability* The stability of SPCA in oxalated serum subjected to different temperatures for varying intervals of time is shown in table 8

*Precipitation by CO<sub>2</sub>* SPCA is not precipitable by CO<sub>2</sub> from oxalated serum diluted 1 to 10 with distilled water. All the activity is demonstrable in the supernatant.

*Adsorption by BaSO<sub>4</sub> or Seitz Filter* Serum was treated with BaSO<sub>4</sub> according to the procedure for adsorbing prothrombin. Its SPCA was removed incompletely.

TABLE 8—Stability of SPCA Activity at Various Temperatures

56	30 min	0

FIG. 4—SPCA SENSITIVITY TO VARYING pH's

and erratically. If, however, the serum was oxalated prior to such treatment, the SPCA was removed quantitatively.

Oxalated serum (25-40 cc) filtered through a Seitz pad (Hercules Type S, size 13, diam 3.6 cm) was devoid of both SPCA and prothrombin activity.

*Sensitivity to Various Hydrogen Ion Concentrations* Oxalated serum was brought to various pH's by the addition of small amounts of acetic acid or sodium hydroxide while the mixture was constantly agitated. After being kept at these pH's for two

hours at room temperature the sera were readjusted to a pH of 7.7 to 8.3 and their SPCA activities immediately determined (fig. 4)

*Behavior of SPCA to Dialysis* The SPCA activity of oxalated serum dialyzed for 25 hours at 9°C in a cellophane bag against oxalated physiologic saline solution was essentially unchanged

*Heterogeneity of SPCA* Dog serum (prothrombin free) can accelerate prothrombin conversion in either dog or human plasma, and its SPCA activity is greater than that of human serum. It should be emphasized that these results are obtained whether the diluent of the plasma-serum mixture is dog, or human, BaSO<sub>4</sub> plasma. Rabbit serum (prothrombin free) also showed excellent SPCA activity on human plasma prothrombin.

### DISCUSSION

Recently various investigators<sup>4, 5</sup> have described clot promoting substances, distinct from thromboplastin and thrombin, which arise *de novo* during blood coagulation. The serum Ac-globulin of Ware et al.<sup>4</sup> evolves from plasma Ac-globulin which itself is relatively inert. Conversion of the plasma component into the serum moiety is said to be affected by extremely small amounts of thrombin. Owen<sup>5</sup> Factor VI (prothrombinase) arises in a mixture of thromboplastin, ionized calcium, prothrombin and Factor V.

Both serum Ac-globulin and Factor VI catalyze the conversion of prothrombin to thrombin. To assay the former, an adaptation of the two stage prothrombin method is used.<sup>3</sup> Factor VI is measured by the amount of additional thrombin evolved from prothrombin in oxalated plasma following addition of the above described reaction mixture in which Factor VI has developed. For both procedures purified prothrombin is required.

In the one stage prothrombin method the clotting time reflects, *inter alia*, the concentration of prothrombin and the velocity of its conversion to thrombin. Modification of this method by dilution with BaSO<sub>4</sub> plasma lends itself well to the study of serum factors which affect the speed of this reaction. This technic dispenses with purified components or isolated systems, and is no more complicated than the routine one stage dilution technique for the determination of plasma prothrombin.

The effect of serum in enhancing the prothrombin activity of plasma is not referable to thrombin, thromboplastin or substances obtainable from platelets. The factor acts apparently on the velocity of prothrombin conversion to thrombin. Accordingly it was designated serum prothrombin conversion accelerator (SPCA), pending further investigation regarding its possible identity with other substances having similar physiologic properties.<sup>1, 2</sup>

SPCA is distinct from the labile factor which also influences the velocity of prothrombin conversion. The ability of serum to reactivate the prothrombin activity of stored plasma is not due to SPCA. This substantiates the conclusions of other investigators that serum contains labile factor.<sup>10, 11</sup> That SPCA has negligible effect on the velocity of thrombin evolution in stored plasma in

which labile factor has largely deteriorated indicates that the latter is necessary for SPCA activity to be fully manifest.

While insufficient data are available to establish the identity or nonidentity of SPCA with Factor VI and serum Ac-globulin, it may be worth-while to compare certain of their properties. Ac-globulin is relatively stable in plasma and serum, is almost quantitatively precipitated from aqueous solution at pH 5.4, is not adsorbed by barium carbonate, and seems to be sensitive to alkaline pH's.<sup>1,2,3</sup> SPCA is similarly stable and sensitive to alkaline pH's. It is, however, not precipitated from diluted serum by CO<sub>2</sub> (pH 5.8) and is adsorbable by barium sulfate from oxalated serum. If SPCA is identical with Ac-globulin the factor is more stable in serum than in purified form since in the latter state about one-half is destroyed at 37°C within 30 minutes,<sup>4</sup> whereas only about 20 per cent of SPCA is destroyed in serum at this temperature within four hours.

There is one important distinction between SPCA and serum Ac-globulin. The latter arises from the action of thrombin on plasma Ac-globulin which, as an accelerator of prothrombin conversion, is relatively inert.<sup>2,3</sup> Very potent preparations of serum Ac-globulin were obtained from plasma to which highly purified thrombin had been added. In contrast, we were unable to produce SPCA in plasma by adding thrombin. In subsequent publications,<sup>6</sup> furthermore, data will be presented indicating that very little, if any, SPCA could be demonstrated in various pathologic states, despite the fact that thrombin had been formed as indicated by clotting as well as by substantial differences between the prothrombin content of the plasma and that of its respective serum.

Owren<sup>5</sup> concludes that Factor VI is identical with Fischer's<sup>25</sup> autocatalytic clot promoting agent which arises during coagulation. If this is so, SPCA is not Factor VI, since Fischer states that serum is devoid of this agent.

#### CONCLUSIONS

1. The addition of oxalated serum to oxalated plasma accelerates the conversion of prothrombin to thrombin in the presence of optimal amounts of thromboplastin plus calcium.
2. The serum agent responsible for this effect is distinct from thrombin, thromboplastin or labile factor. We have called it the serum prothrombin conversion accelerator (SPCA).
3. A method for its assay is presented.
4. Some of its physiologic and biochemical properties are described.

# REFINED LIVER EXTRACT IN TROPICAL MACROCYTIC ANEMIA

By J C PATEL, M D , Ph D , AND Y M BHENDE, M D

## INTRODUCTION

NAPIER<sup>1</sup> and Moore et al<sup>2</sup> wrote a few years ago that therapeutic observations with different liver extracts, material containing the extrinsic (food) and/or the hemopoietic factors, would alone help to elucidate the etiology of tropical or nutritional macrocytic anemia(s). Emery and Hurran<sup>3</sup> advocated dosage requirements, based on units, in the treatment of more complex macrocytic anemias and hoped this might lead to the resolution of the divergent views held by different authors on the relative efficacy of crude and refined liver extracts.

Since the early observations of Wills and her associates<sup>4,5</sup> on the inactivity of refined or pure liver extracts in the treatment of tropical macrocytic anemia (T M A ) a number of workers have reported its effectiveness in varying doses. Napier et al<sup>6</sup> found Anahaemin potent in a few cases of T M A. Foy and Kondi<sup>7</sup> and Fairley<sup>8</sup> treated cases of nutritional macrocytic anemia (N M A ) with larger doses of Anahaemin and found it effective. Trowell,<sup>9</sup> in East Africa, observed that 12 ml of Anahaemin per week was required to produce an optimum response in his 6 cases of T M A. Sundaram<sup>10</sup> treated successfully 13 cases of T M A with 12 ml of refined liver extract. Moore et al<sup>2</sup> used Reticulogen in the treatment of 25 cases of N M A of pellagra with good results.

## MATERIAL AND METHODS

The present paper reports the use of refined liver extracts in a series of 45 cases of T M A as found in Bombay. The refined liver extracts used were Anahaemin (British Drug House) Examen (Glaxo) Reticulogen (Lilly) and Examen New Potency (Glaxo).

The cases presented were studied during the last eight years. Thirty one of the 45 cases were investigated in detail according to the procedure advocated by us<sup>11</sup> the rest have been included in this report because they were cases of severe anemia with (1) clinical history and findings similar to those which were diagnosed as T M A after a thorough investigation (2) a high color index (3) predominant macrocytosis in the peripheral blood smear (4) free hydrochloric acid in the gastric juice with or without histamine stimulation. We may emphasize that though the presence of free hydrochloric acid in the gastric juice is in favor of the diagnosis of T M A (as opposed to Addisonian pernicious anemia) its absence does not negate such a diagnosis.<sup>11,14</sup>

All the patients except one had an initial blood count of less than 3,00,000 red blood cells per cu mm. The patients were kept on the hospital milk diet during their first fortnight's stay and later were on an entirely vegetarian diet consisting of chapatis (home made bread of wheat flour) rice dal (a preparation made from pulses) and green and cooked vegetables. It has been our experience (Patel<sup>12</sup>) that no hematologic improvement occurs in patients kept solely on this diet. Besides this hospital diet these cases of anemia were given an alkaline geotian mixture if the gastric analysis showed normal hydrochloric acid content and an acid mixture if there was hyp acidity or achlorhydria. Iron was not administered. Vitamins of the B complex group were administered by mouth or by injection to some of the later cases in addition to the refined liver extract in question. The efficacy of the liver extract therapy was assessed

in the earlier cases by the reticulocyte response and improvement in the level of the red blood cells and of the hemoglobin during a period of ten days and in the latter part of the work by the formula of Dyke and Della Vida  $I = (0.93 - 0.214)EO$  where  $I$  is the average weekly increase in red cells during the first two weeks of treatment and  $EO$  is the red cell count before the treatment. Most of the investigations were carried out by us personally, a few gastric analyses were done by the clinical laboratory. The results are given in table 1 which should be consulted for the details of the case histories which follow.

in agreement with the findings of Trowell<sup>9</sup> and Sundaram<sup>10</sup> When given in larger total doses (larger than 12 ml), the response continues for a longer period

### *Group II—Twelve Cases Treated with Examen*

*Case 4* A 35 year old female complained of general weakness and stomatitis of six months duration RBC 1.88 mill per cu mm, Hb 8.99 Gm per 100 ml M.C.V. 127.0 cu  $\mu$  M.C.H.C. 39 per cent She was given 2 ml Examen The highest reticulocyte count was 4.2 per cent on the fifth day Improvement in ten days was optimum but was not maintained and the blood count fell slightly in the next ten days

*Case 18* A male aged 25 RBC 1.2 mill per cu mm., Hb 5.35 Gm per 100 ml M.C.V. 137 cu  $\mu$ , M.C.H.C. 33.5 per cent Response to 4 ml of Examen in ten days was optimum

*Case 12.* A male aged 24 years was suffering from diarrhea stomatitis and attack of vomiting of one month's duration Examination of the blood showed RBC 1.34 mill per cu mm Hb 3.40 Gm per 100 ml He was treated with 8 ml of Examen given in the first two days A maximum reticulocyte response of 36 per cent was recorded on the fifth day and the improvement was optimum

*Case 16* A 30 year old male was admitted for intermittent diarrhea for the previous three months and low fever and general weakness of six weeks duration RBC 2.48 mill per cu mm Hb 10.38 Gm per 100 ml M.C.V. 113.0 cu  $\mu$  M.C.H.C. 36.9 per cent He had a complicating ulcerative colitis and his blood Wassermann reaction was positive There was a histamine-fast achlorhydria He did not respond to Examen 10 ml given in the first four days neither did he respond afterwards to 60 ml (5 ml daily) of crude liver extract (Lilly) He was given arsenic injections for his syphilis while he was having crude liver extract He left the hospital against advice without any improvement

### *Comment on the Cases in Group II*

Cases 3, 5, and 6 responded well to 12 ml to 14 ml of Examen Case 7 responded poorly to 20 ml of Examen but subsequently showed a better, though not an optimum response, to Campolon 75 ml given in twenty days When Examen was given in large doses of 22 ml in Case 14 and Case 15, of 20 ml in Case 17, and of 32 ml in Case 11, the response was not only adequate but persistent for many days afterwards In this series of 12 cases of T.M.A. treated with Examen, 2 showed adequate response to a small dose of 2 ml and 4 ml, and, 3 to a total dose of 12 to 14 ml, but neither these dosages were able to sustain the improvement beyond a period of ten to fourteen days In 4 patients, a larger dosage of 22 ml to 32 ml was not only able to produce a good response, but this response was maintained for days afterwards In 1 case, 10 ml of Examen did not produce any improvement, but later this case did not respond to crude liver extract either Another showed a poor response to 20 ml of Examen, he was immediately afterwards treated with Campolon (Bayer), 75 ml But even with Campolon the response was comparatively poor and slow

### *Group III—Two cases of T.M.A. Treated with Reticulogen*

*Case 8* A male aged 17 years complained of recurring attacks of stomatitis and low fever for four months He suffered from diarrhea while under observation in the wards The spleen was palpable and there was a hemic murmur in the precordial area RBC 1.46 mill per cu mm Hb 6.05 Gm per 100 ml M.C.V. 115.0 cu  $\mu$  M.C.H.C. 34.4 per cent The Van den Bergh reaction was indirect positive He was treated with Reticulogen 0.5 ml daily for eight days The response was poor Subsequently he responded well to Campolon

*Case 9* A male aged 38 years complained of general weakness of two months duration There was history of diarrhea the previous year He was very poorly nourished The spleen and the liver were both palpable RBC 1.36 mill per cu mm Hb 4.84 Gm per 100 ml M.C.V. 108 cu  $\mu$  M.C.H.C. 33.8

per cent The Van den Bergh reaction was indirect positive He was treated with Reticulogen 8 ml in eight days the response was adequate

#### *Group IV—Cases of T M A Treated with Examen (New Potency)*

Towards the end of 1944 Emery and Hurran<sup>2</sup> had prepared a refined liver extract which contained a minimal amount of solids and was consistently effective in a small dosage in Addisonian pernicious anemia One ml was extracted from 60–80 Gm of liver This liver extract (Examen New Potency [N P]) has been used by us in the treatment of 27 cases of T M A since 1945 It was used in varying doses 10 ml in Case 19 12 ml in Case 20 and 8 ml in Case 25 it produced an optimum response in all In 2 out of the 3 the response was maintained for a few days afterwards Six ml of Examen (N P) (1 ml daily for first six days) was given to 6 cases (Nos 22, 24 25 26 27 and 28) In 2 (Nos 22 and 25) not only did it produce an optimum response but the effect was maintained for a further period of about three weeks In the remaining 4 cases (Nos 24 26 27 and 28) the same dosage produced an optimum response In Case 23, 5 ml of Examen (N P) did not produce any response Later Plexan crude liver extract 24 ml was equally ineffective In 5 cases (Nos 29 30 31 34 and 35) Examen (N P) was administered in the dosage of 1 ml for the first three days a total of 3 ml for each case In 3 (Nos 29 30 and 34) there was an optimum response in 1 (No 35) a suboptimal and in 1 (No 31) no response at all Case 31 was admitted in the general hospital 15 days after delivery (a stillborn child) displaying pregnancy anemia She left the hospital without further treatment Ten cases (Nos 33 37 38, 39 40 41 42 43 44 and 45) were treated with 2 ml of Examen (N P) It produced an optimum response in 5 cases (Nos 33 38 42 43 and 45) suboptimum response in 4 (Nos 37 39 40 and 41) and no response in the last case (No 44) Case 33 not only showed an optimum response to 2 ml of Examen (N P) but the response continued for a period of thirty four days Case 44 who had a positive Wassermann reaction failed to respond to 12 ml of potent crude liver extract subsequently In Cases 32 and 36 1 ml of Examen (N P) produced an optimum and suboptimal response respectively (Cases 30 32, 33 and 34 have been the subject of a separate report by one of us<sup>12</sup>)

#### *Comment on the Cases in Group IV*

From the above findings we conclude that Examen (N P) produced an adequate hemopoietic response in all cases with the exception of 3 (Cases 23, 31 and 44) A total dose of 2 or 3 ml seems adequate to obtain an optimum response in the majority of cases In an occasional case, even 1 ml has given satisfactory results When given in the larger doses of 6 ml, not only is the response satisfactory but its hemopoietic effect continues for many days afterwards

#### DISCUSSION

No better initial response is likely to be obtained in an uncomplicated case of Addisonian pernicious anemia by giving a dose larger than is necessary to produce an optimum response as defined above (Emery and Hurran<sup>2</sup>) Probably the same statement is applicable to the treatment of T M A In a total of 45 cases of T M A treated with refined liver extract, 39 responded satisfactorily, 32 gave an optimum response and 7 suboptimum response The 6 cases which did not respond to refined liver extract were as follows Case 8 did not respond to Reticulogen but later responded satisfactorily to crude liver extract Cases 7, 16, 23 and 47 not only did not respond to refined liver extract but failed as well to respond to crude liver extract administered subsequently Case 31, pregnancy anemia, did not respond to refined liver extract during her stay of one week but then she did not stay in the hospital long enough for detailed observations There were only 2 cases, then, which did not really respond to refined liver extract

The above observations are in general agreement with those of Foy and Kondi,<sup>7</sup> Fairley,<sup>8</sup> Trowell<sup>9</sup> and Sundaram,<sup>10</sup> but differ from their findings in that the dose found effective in our series is much smaller than that used by any of them.

Some textbooks<sup>15 16</sup> recommend that any liver extract, no matter of what type, should be given in a certain dose volume (e.g., 2 ml or 4 ml twice a week) in order to obtain a satisfactory remission in Addisonian pernicious anemia and the allied conditions. Dyke and Della Vida<sup>12</sup> have adopted the arbitrary criterion that any liver extract producing a good response with a total dosage of less than 10 ml over the first fortnight should be regarded as sufficiently potent for therapeutic use. There are no similar criteria available for T M A. If the above criteria are applied to T M A it can be deduced, from our results, that refined liver extracts used in this series were definitely of therapeutic value, particularly the Examen (N P). But, as Emery and Hurran<sup>3</sup> have pointed out, the volume is not by itself an indication of its potency. It is the therapeutically active principle of the solid content which is the deciding factor, and this can be dissolved in varying quantity of the fluid-base. In the absence of a reliable and generally accepted *unitage* in assaying the potency of liver extracts,\* the important point is the quantity of the original liver from which the active solids have been extracted. The difference between the efficacy of crude and refined liver extract, expressed in terms of *original liver*, should be the ultimate basis for discussion. Originally it was found that in the treatment of Addisonian pernicious anemia, crude extract derived from 60 to 80 Gm of liver produced a satisfactory response, whereas the equivalent of 200 Gm of the original liver was required when administered in the form of a refined liver extract. In the process of purification, activity might be lost in the discarded side fractions, it might even be totally destroyed. Or, the hemopoietic activity of a liver extract may be dependent on the simultaneous presence of more than one substance as postulated by Jacobson and Subbarow<sup>17</sup> some years ago. Possibly some of these factors might be removed during the concentration or purification. Emery and Hurran<sup>3</sup> claim to have produced a refined liver extract (Examen N P) containing in 1 milliliter, the equivalent of 60 to 80 Gm of liver, which in 1 ml dosage was effective in 3 cases of Addisonian pernicious anemia, thus removing the discrepancy between the response to refined and crude extracts in terms of the original liver.

The average amount of crude liver extract required to produce a satisfactory response in T M A varies with the brand. Twenty ml (equivalent to 100 Gm of original liver) of Campolon was used by Napier<sup>1</sup> and by Wills and Evans.<sup>4</sup> Twelve ml of Plexan (equivalent to 90 Gm of original liver) and 8 ml of Chemilon (Dr Rao's laboratory) (equivalent to 100 Gm of original liver) were considered necessary to produce a satisfactory response by Patel.<sup>12</sup> This shows that the crude liver extract derived from about 90 to 100 Gm of original liver is effective in an average case of T M A. One to 2 ml of Examen (N P) which is found to be effective in T M A will be derived from 60 to 120 Gm of the original liver. Thus, the discrepancy between the response to refined and crude liver extracts in

\* The United States Pharmacopoeia has developed standards for *unitage* of liver extracts which appear to be reliable and are based on assays in human cases of Addisonian pernicious anemia. *Edit*

T M A in terms of the original liver, which was so noticeable in the past, is now insignificant. It will be noticed that the amount of active principle (original liver) needed to produce a satisfactory response is more than that required in Addisonian pernicious anemia, but otherwise the deficiency in the majority of cases of T M A seems to be similar to that in Addisonian pernicious anemia. Moore et al.<sup>2</sup> working in the U S A discussing their successful treatment of N M A with highly 'purified' liver extract (Reticulogen) concluded that either (1) the N M A found in the United States differed in some fundamental respect from the N M A seen in India, or, that (2) the 'purified' liver extract used by them contained some hypothetic substance not found by Wills<sup>4</sup> in Anahaemin. From the therapeutic results obtained in the present series it can be reasonably stated that tropical macrocytic anemia in India does not differ fundamentally from the nutritional macrocytic anemia found in the United States or elsewhere.

Obviously, then, calculating in terms of original liver and comparing the responses obtained by the "crude" and the newer "refined" extracts in Addisonian pernicious anemia and in T M A it can be inferred that a considerable amount of active principle was probably not extracted in the older "refined" liver extracts, and, hence, the discrepancy in the results obtained in the past both in Addisonian pernicious anemia and T M A. This might, possibly also, be the explanation of the conflicting results obtained in the past by various workers in the treatment of T M A with refined liver extracts. Fairley<sup>8</sup> believed that there was no advantage—on the contrary a disadvantage of a higher cost—with the use of refined liver extract in the treatment of T M A. This is true if one has to give large doses, but if 3 ml or less be considered a satisfactory dose to obtain an optimum response, the cost will not be much higher and there would be the added advantage of less pain locally and of reduction in the systemic reactions to the injections of the liver extracts.

#### SUMMARY

- 1 A series of 45 cases of T M A treated with refined liver extract is reported.
- 2 Refined liver extract was found to be effective in 39 cases.
- 3 It was found that 2 or 3 ml of refined liver extract (Examen N P) was sufficient to produce an optimum response.
- 4 As judged from therapeutic observations, it is suggested that in the majority of cases of T M A the deficiency is similar to that in Addisonian pernicious anemia, though the mode of production of the deficiency may not be the same.

#### ACKNOWLEDGMENT

Our thanks are due to Dr R. Row, Hon. Director P G. Singhance Hindu Hospital Bombay where all the cases were treated for permission to publish these reports, and the firms concerned for the generous gift of liver extracts.

## A CASE OF CYCLICAL AGRANULOCYTOSIS WITH MARKED IMPROVEMENT FOLLOWING SPLENECTOMY

By H W FULLERTON, M D , M R C P , AND H L D DUGUID, M B , CH B

IN 1946, Vahlquist<sup>1</sup> described a case of true cyclical agranulocytosis and summarized the findings in the other 5 cases reported in the literature before that time. Since then, the number has been increased to 7 by an example published in 1946 by Reznikoff.<sup>2</sup> In 5 of these cases, the condition had commenced in infancy and was characterized by periods of complete or almost complete disappearance of neutrophil leukocytes from the peripheral blood at regularly recurring intervals of approximately 21 days. Pyrexia and ulceration of the mouth were the main features of the attacks. Of the other 2 published cases, one was a girl of 18 years<sup>3</sup> and the other a woman of 43 years.<sup>4</sup> Some examples of agranulocytosis occurring repeatedly at the time of menstruation have been properly excluded from the group of idiopathic cyclical agranulocytosis because the possibility of the women affected having taken drugs (e.g., amidopyrine) at the onset of menstruation was not excluded.

From a perusal of the published case reports it is obvious that the characteristic features of cyclical agranulocytosis have been intriguing enough to stimulate much investigation into the pathogenesis. The report by Imerslund<sup>5</sup> is the most striking example of the extensive nature of the investigations which have been performed in the study of this peculiar condition. Her patient, a boy of 16 years who had suffered from the disease since the age of 14 months, was subjected to very full hematologic, biochemical, bacteriologic and endocrinologic studies, but no abnormalities which could clearly be correlated with the leukocytic changes were discovered. Therapeutic efforts have been equally energetic and varied. Pent-nucleotide, blood transfusion, yellow bone marrow, the various vitamins, liver extract, anterior pituitary extract, ultra-violet light and short-wave therapy are some but not all of the measures which have been used, and none of them has succeeded in preventing or even in significantly modifying the persistently regular occurrence of agranulocytosis and the associated symptoms. Splenectomy has been done in only one of the reported cases, and was followed by no notable improvement.

The patient to be described is apparently unique, first because he is a man who developed cyclical agranulocytosis in advanced adult life, and second, because splenectomy has greatly modified the recurrent falls in the neutrophil leukocytes and has abolished his symptoms completely.

### CASE REPORT

J S, male, age 62 years was admitted to Aberdeen Royal Infirmary on June 6 1946

From the Department of Medicine, University of Aberdeen Aberdeen Scotland

**History of present illness** In October 1945 he thought he had fever felt generally unwell and had a course of sulphadiazine tablets (total 28 Gm) In January 1946, he had a painful throat and conjunctivitis and underwent another course of sulphonamides Sore throat recurred 10 February 1946 and, in addition, he developed boils to the neck and an ischio-rectal abscess Another course of sulphadiazine was taken at this time In March he again had pain in the throat and for the fourth time had sulphadiazine orally

Unfortunately, it was impossible to obtain exact details of these illnesses but the patient was quite definite that on each occasion infection had developed *before* sulphonamide was taken

Shortly before admission to hospital the ischio-rectal infection recurred and he had sore throat

**Past history** Seventeen years ago he developed rheumatoid arthritis which was treated by tablets, he had no injections This kept him from his work as a laborer for five years He was then able to work and had little disability except for occasional stiffness and pains in the knees for which he has taken aspirin During the 1939-45 war he was a cement worker

FIG. 1. CHART SHOWING VARIATIONS IN THE ABSOLUTE NUMBER OF NEUTROPHIL POLYMORPHS  
PN represents penicillin-nucleotide therapy, BEN benadryl, PYR. pyridoxine, SD sulphadiazine, SP splenectomy. The cross-hatched areas represent periods of pyrexia.

**Family history** Two brothers, one is alive and well the other died of consumption at the age of 40. His only sister is dead cause of death unknown to patient. Mother died at 38 years cause unknown. Father died in his early forties as a result of pneumonia. The patient is married and his two sons and one daughter are alive and well.

**Physical examination** He was a well-nourished well-colored man. There was some thickening about both wrists and the metacarpo-phalangeal joints with slight limitation of movement. B.P. 155/85. The heart was not enlarged and the sounds were normal. Examination of the various systems revealed no notable abnormalities, in particular it was noted that the spleen was not palpable.

**Course of the illness** Between June 1946 and March 1947, the patient suffered from twelve attacks in each of which the neutrophil polymorphs disappeared entirely from the peripheral blood usually for a period of four to five days. The intervals between the attacks were remarkably regular, varying from twenty-three to twenty-eight days (see fig. 1). Each attack was characterized clinically by malaise, anorexia, drowsiness, headache, pyrexia and variously localized infections. Inflammation and edema of the throat and

tonsils were constant features of the attacks. Conjunctivitis, iritis, blepharitis, recurrences of the ischio-rectal infection, painful superficial ulcers on the gums and tongue and areas of acute inflammation to the skin occurred in various combinations. Meatal depression became more marked with each succeeding attack. As the granulocytes reappeared in the blood, the various infections rapidly disappeared and the pyrexia settled, the patient's well being was quickly restored and he helped cheerfully in carrying out light work in the ward.

The variations in the absolute number of neutrophil polymorphs are presented graphically in figure 1, which shows also the time intervals between the midpoints of the phases of agranulocytosis. It is to be

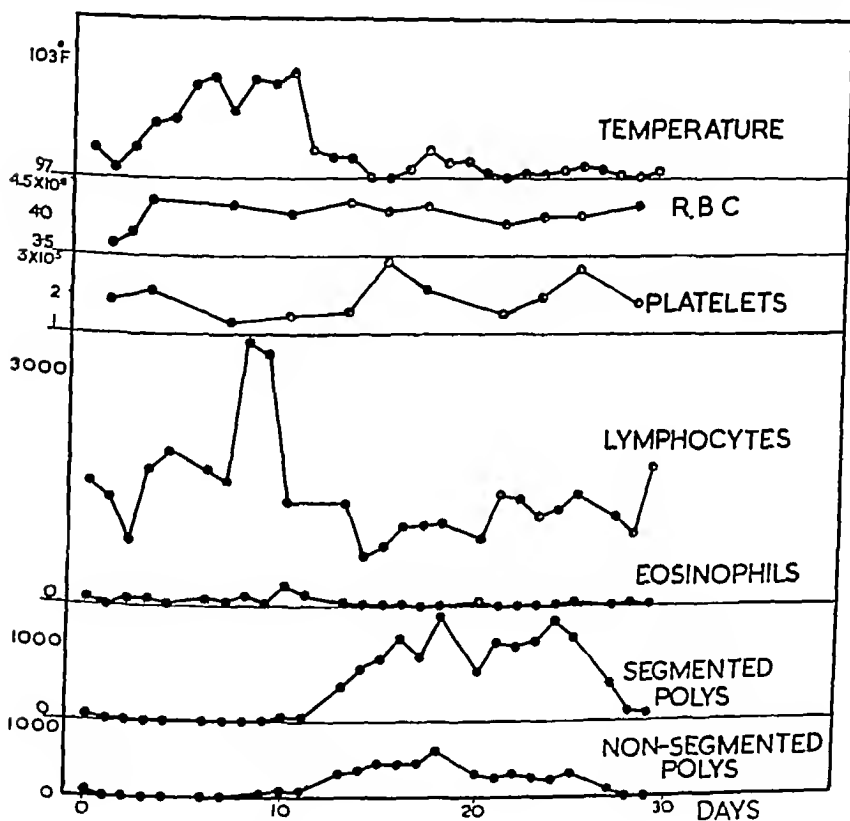

FIG. 2. CHANGES IN ALL COUNTS DURING ONE TYPICAL CYCLE

noted that between attacks the neutrophil polymorphs did not reach normal but were between 1 and 3 thousand per cu. mm. except on one occasion (217th day) when a figure of nearly 6000 was reached; this coincided with a recurrence of the ischio-rectal infection and was the only occasion on which infection occurred apart from the phases of agranulocytosis.

**Laboratory investigations.** The blood Wassermann reaction was negative. Throat swabs usually gave a growth of staphylococcus aureus. Blood cultures were sterile. X-ray of chest was normal. X-ray of the nasal sinuses showed chronic infection of the antra. Blood counts were done almost daily throughout the patient's stay in hospital.

In the period before splenectomy, in March 1947 (290th day) the outstanding feature was the comp-

disappearance of neutrophil polymorphs for four to five days every three to four weeks. The variations in these and other cells throughout one complete cycle are presented in figure 2. It is to be noted that the disappearance of the polymorphs preceded the rise of temperature. Throughout the presplenectomy period the hemoglobin and red cells showed no significant variations from a level of 80 per cent (Haldane) and 40 millions. The platelets varied between 100 000 and 350 000 per cu mm and although the lowest figures were found during phases of agranulocytosis considerable variation occurred between attacks. The eosinophil polymorphs varied from 0 to 700 per cu mm but their number showed no correlation with the neutrophil polymorphs. The lymphocytes always increased during an agranulocytic phase the extent of the increase varied with a maximum of 6 700 per cu mm. The basophils and monocytes showed no notable changes.

## SPECIAL INVESTIGATIONS

*Bone marrow studies* Because it seemed important to determine whether the periodic disappearance of neutrophil polymorphs was due to a failure in the produc-

tion of these cells by the marrow, or to their excessive destruction after delivery into the blood, eight aspirations of sternal marrow were performed at intervals of a few days throughout one typical cycle. The differential counts of the nucleated marrow cells are presented in table 1. It is to be noted that the percentage of normoblasts varies between 9.2 and 43.6. Since no significant variations occurred in the red cell count, it may be presumed that the absolute number of normoblasts remained fairly constant and the variation in the percentage figures is due simply to changes in the other marrow cells, especially the neutrophil polymorphs and their precursors. In other words, the total cellularity of the marrow is greatest when the percentage of normoblasts is lowest, and the absolute increase in the granular cells is of greater degree than is indicated by the percentage figures in the table. In figure 3, the neutrophil cells and their precursors in the mar-

row have been charted so that their course can be compared with simultaneous variations in the number of neutrophil polymorphs in the blood. It is clear that a rise, first in myeloblasts and premyelocytes and then in myelocytes, in the marrow precedes the appearance of neutrophil polymorphs in the blood, and the early forms of the myeloid series decrease in the marrow a few days before the fall of neutrophil polymorphs in the blood. It follows that the underlying cause of the phases of agranulocytosis was a periodic failure of the marrow to produce neutrophil poly-

FIG. 3. CHART SHOWING CORRELATION BETWEEN MARROW FINDINGS AND BLOOD LEUKOCYTE COUNT DURING A TYPICAL CYCLE

morphs, and it is unnecessary to postulate any increase in their destruction to explain the findings. There is no evidence of a maturation defect in the marrow since even the myeloblasts are markedly decreased in the agranulocytic phase. It may be pointed out, however, that if reliance had been placed on a single marrow examination wrong conclusions might have been drawn. For example, on the eleventh day of the cycle studied (see fig. 3), a considerable number of myeloblasts and premyelocytes (12.0 per cent of the marrow cells) were present with few

myelocytes and polymorphs and only 135 neutrophil polymorphs per cu mm in the blood. This could have been interpreted as a maturation defect in granular cell formation, whereas the true explanation is that formation of mature cells from the regenerating myeloblasts and premyelocytes had not yet occurred at the time of the aspiration. We believe that erroneous conclusions have been drawn by several writers from the results of a single marrow examination in agranulocytosis.

*Adrenaline Test* During an agranulocytic phase and mid-way between two attacks, 10 cc adrenaline was injected subcutaneously and white cell counts were performed at intervals after the injections. In the phase of agranulocytosis no significant change in the neutrophil polymorphs was found following the injection (before injection, 23 neutrophil polymorphs per cu mm, maximum after injection 106), whereas between attacks the neutrophil polymorphs were increased from 1670 to a maximum of 2600, 55 minutes after the injection.

*Transfusion of Patient's Plasma* In an attempt to discover if a factor with a depressant action on leukopoiesis circulated in the patient's plasma at regular intervals coinciding with the phases of agranulocytosis, one pint of blood was removed from the patient on two occasions (at the beginning of an attack and mid-way between attacks) and the plasmas were injected intravenously into another subject. On both occasions no significant effect on the recipient's leukocytes occurred. It is realized that this experiment is a crude one and that the negative result does not rule out the possibility that a depressant factor might have been demonstrated by suitable animal experiments.

*Sex Hormone Excretion* The regular occurrence of the crises in cyclical agranulocytosis has naturally led to a comparison with menstruation, and to the suggestion that the underlying disturbance might be a rhythmical disturbance of sex hormone production. Imerslund<sup>6</sup> had prolactin and folliculin titrations in the urine done every other day throughout one cycle in her patient, a boy of 16 years. Three times, the excretion of folliculin was a little greater than the normal range, on the first and third of these occasions the polymorphs were low, on the second they were high. No notably abnormal values for prolactin excretion were found. Thompson<sup>7</sup> considered that in his patient, a man of 25, the number of the neutrophil polymorphs could be correlated with the urinary excretion of female sex hormone but as the investigations were continued during only a short part of one cycle and were not repeated, the findings are not convincing. Perhaps the strongest evidence against the sex hormone theory is provided by the cases of Embleton<sup>4</sup> and Doan,<sup>3</sup> the only true examples of idiopathic cyclical agranulocytosis we have been able to discover in women of reproductive age. In both cases, no relationship could be observed between the times of menstruation and the occurrence of phases of agranulocytosis. We were unable to have estimations of prolactin and folliculin excretion carried out in our patient but the urinary 17-ketosteroids were estimated twice, at the beginning of an attack a figure of 7.3 mg/24 hours was obtained and mid-way between attacks the figure was 7.5 mg.

#### TREATMENT

*Penicillin* As each attack of agranulocytosis developed, our patient was given penicillin intramuscularly and this was continued until the neutrophil polymorphs

had reappeared in significant numbers, usually a total of approximately 2 million units was given over a period of about ten days.

*Pentnucleotide* Intramuscularly was given in the first attack observed in hospital (see fig. 1). No clear-cut effect was produced and as undesirable reactions followed the injections, this treatment was not repeated.

*Anti-histamine drugs* In intermittent hydrarthrosis effusion into the affected joint often occurs with remarkable regularity, so that in this respect at least the condition is similar to cyclical agranulocytosis. The possibility that an allergic disturbance may be responsible for intermittent hydrarthrosis and the fact that this mechanism has been held to explain some cases of agranulocytosis<sup>7, 8</sup> led us to try the effects of benadryl and lertigon in our patient. Benadryl was given in a dose of 250 mg daily from days 140 to 152 (see fig. 1). The drug was purposely started at a time when the neutrophil polymorphs had started to fall. No influence on the usual course of the illness was observed. Lertigon (histamine azoprotein, Parke Davis and Co.) was commenced on day 161 in a dose of 0.01 cc, which was gradually increased to a maximum of 1.25 cc on day 200. Again the pattern of the polymorph curve was undisturbed.

*Pyridoxine* In view of recent reports of the efficacy of pyridoxine in the treatment of acute agranulocytosis,<sup>9-11</sup> this drug was given intramuscularly (total 300 mg) and orally (total 450 mg) over a period of six days. Treatment was started on day 224 while the neutrophil polymorphs were falling (see fig. 1). The dosage employed was rather less than that usually recommended but the complete absence of any influence on the course of the polymorphs makes it unlikely that larger doses would have been effective.

*Sulphadiazine* Prior to admission to hospital our patient had taken several courses of sulphadiazine. On each occasion, infections had developed before sulphadiazine was taken and the attacks of agranulocytosis continued for many months after the last doses of the drug, so that it seemed most unlikely that sulphadiazine had played any part in causation. However, to confirm this view, a total of 25 Gm sulphadiazine was given orally (days 237-241). Again the usual course of the polymorphs was unchanged.

*Splenectomy* The decision to perform splenectomy cannot be regarded as having a very rational foundation, it was based on the consideration that the role of the spleen in regulating the numbers of the various formed elements in the blood is not yet fully understood, and that long continued leukocytosis may follow splenectomy. We were familiar with the reports of cases of chronic (noncyclical) granulocytopenia in which the operation has proved successful.<sup>1-16</sup> In such cases, however, the general view is that the granulocytopenia is due to excessive phagocytosis of polymorphs in the spleen, and Wiseman and Doan<sup>17</sup> include splenomegaly and hyperplasia of the myeloid series in the marrow among the diagnostic criteria. In our patient there were several important differences: the spleen had never been palpated, in the phases of agranulocytosis there was aplasia of the myeloid series in the marrow, and the results of serial marrow and blood studies provided no evidence that excessive peripheral destruction of neutrophils occurred. At the time when our decision was made we had found no record of splenectomy in true cyclical agranulocytosis, the report of Reznikoff<sup>2</sup> was not at that time available to us.

His patient was a boy of 18 years who, since infancy, had suffered from cyclical agranulocytosis. Following splenectomy the absolute numbers of neutrophil polymorphs in the blood were not significantly altered, although the degree of prostration during the leukopenic phases was considered to be less.

Splenectomy was performed on the 290th day by Mr G Gordon Bruce. No accessory spleens were found. Dr W M Davidson reported on the spleen as follows: The spleen was enlarged to some three or four times the normal size and was of a firm consistency. The cut surface was fairly uniform, the malpighian corpuscles and trabeculae being visible but not prominent. Microscopically, there were no outstanding features. A small amount of iron pigment was present but there was neither erythrocyto- nor leukophagocytosis to be seen. The central arteries of the malpighian corpuscles showed a hyaline degeneration, and this had extended into the small vessels in the germ center. A slight degree of fibrosis was present in the pulp tissue and, at one or two points, small collections of cells suggested foci of hemopoiesis, but not very definitely. There was no amyloid change.

The operation was followed quickly by a marked leukocytosis which reached a maximum of 18,900 with 83 per cent neutrophil polymorphs five days after operation (see fig 1). Thereafter, the white cells fell rapidly but, in contrast with every phase of leukopenia observed before operation, the neutrophil polymorphs did not completely disappear, after falling to 406 per cu mm (day 299) they commenced to rise again. Another marked fall occurred about a month later (lowest number of neutrophil polymorphs 90 per cu mm on day 326), but since then, although fluctuations have occurred, the lowest number of neutrophil polymorphs has been 640 per cu mm on day 447. Thus, splenectomy has not been followed by a normal white cell picture. Fluctuations of considerable magnitude have occurred but at no time have the neutrophil polymorphs completely disappeared from the peripheral blood, and this change has been accompanied by a great improvement in the patient's health, since no episodes of pyrexia and no infections have developed in the period of 190 days during which he was carefully studied following the operation. Two months later (254 days after operation) the patient was seen again and reported continued good health and freedom from infections. The white cell count was 4050 per cu mm with 16 per cent neutrophil polymorphs (648 per cu mm), Hb 106 per cent, R B C 520, C I 1 or 1\*.

#### DISCUSSION

Investigations in the case described above failed to reveal a clear cause for the spectacular variations in the neutrophil polymorphs. It cannot be doubted that splenectomy modified the course of the illness markedly, although neutropenia of considerable degree has persisted. This suggests the possibility that the spleen was only one site of a more widespread lesion† but its nature and the mechanism whereby it produced cyclical variations in the myeloid series of cells remain entirely obscure.

\* *Addendum* When last seen 2/2/49 the patient had remained free from infections and the leukocyte count was 8500 per cu mm neutrophil polymorphs 47 per cent, eosinophils 6 per cent, lymphocytes 31 per cent, monocytes 16 per cent.

† Or that its removal resulted in removal of the normal inhibitory effect of the spleen on white cell delivery from the bone marrow to the blood. *Ed*

Judging by the small number of cases reported in the literature, cyclical agranulocytosis appears to be a very rare disease. We feel, however, that it may be more common than is realized because cases may easily be missed. It was only after our patient had been in hospital for several months and the absolute numbers of neutrophil polymorphs had been charted, that the striking cyclical nature of the disturbance was appreciated. Frequent white cell counts over a considerable period are essential if the condition is to be recognized. In several of the cases reported in the literature as examples of chronic granulocytopenia, white cell counts were done so infrequently that cyclical variations, if they were present, could not have been detected. More careful study of patients with chronic leukopenia, particularly if there is a history of recurrent episodes of ulceration of the mouth and other infections, would probably reveal more examples of true cyclical agranulocytosis.

### SUMMARY

1. A case of cyclical agranulocytosis beginning in a man at the age of 62 years is described.
2. The course of the illness was greatly modified by splenectomy, neutropenia continued but phases of complete agranulocytosis and infection ceased.

## CHRONIC NEUTROPENIA FAVORABLE RESPONSE FOLLOWING SPLENECTOMY

By LIEUT HARRY A. WEISS, (MC) U S N , AND LIEUT (JG) WILLIAM T. COLLINS,  
(MC) U S N R

THE ROLE of the spleen in the pathogenesis of neutropenia has been extensively studied in recent years, and two hypotheses have been advanced. Doan and his associates<sup>1</sup> have observed hyperplasia of the phagocytic reticulo-endothelial cells or clasmatocytes of the spleen with an abnormal phagocytosis of the granulocytes, and account for the neutropenia on this basis. They have also applied this concept of selective destruction of cellular elements of the blood to explain the anemia and thrombocytopenia which are frequently associated with the neutropenia.

The second hypothesis, which has been strongly supported by Dameshek,<sup>2,3,4</sup> is that of hypersplenism in which the spleen exerts an abnormal inhibitory effect, probably by means of a hormone, upon the maturation and release of cells from the bone marrow. Dameshek has emphasized this mechanism particularly in idiopathic thrombocytopenic purpura,<sup>2</sup> and also believes that the granulocytopenia which occurs in many types of splenomegaly may be mediated in a similar manner.<sup>3,4</sup>

A case of chronic neutropenia has been studied and is reported because of the significant elevation of the circulating neutrophils following splenectomy.

### CASE REPORT

V E, a 19 year old white male was admitted to the hospital on April 10, 1946 with a diagnosis of diabetes mellitus.

The patient's illness began in August, 1945, while aboard ship in the South Pacific, with symptoms of weakness, lassitude, somnolence, polydipsia, pronounced weight loss and muscular cramps in the legs. On September 20, 1945 he had a brief episode of generalized abdominal cramps and vomiting from which he rapidly recovered. A few days later, a second episode occurred and was accompanied by a mild diarrhea. Physical examination at that time was not remarkable but a blood count revealed leukopenia. Treatment consisted of paregoric and penicillin, and the cramps and the diarrhea ceased. Because of the persistence of the leukopenia, he was transferred to a Fleet Hospital in Manila, P. I. On admission there a physical examination revealed no significant findings. On November 4 a urinalysis disclosed a 4 plus sugar, and subsequently a glucose tolerance test showed a diabetic curve. The diabetes was controlled by insulin and dietary measures and the patient was transferred to a Naval Hospital in Hawaii for further study of the leukopenia. On January 16, 1946, a sternal biopsy was performed and revealed no evidence of blood dyscrasia. His course there was uneventful and on April 10, 1946 he was sent to this hospital.

The patient had been a lifelong resident of Utah until entry into the Navy in July, 1944. From 1937 to 1944, he had sprayed arsenic of lead insecticide in orchards for three to four day periods several times each summer. For one month prior to the onset of the present illness, he had worked in a paint locker on the ship six hours each day but, to his knowledge, had not handled any lead paints. From March to September, 1945, he had received atabrin in prophylactic dosage.

---

From the U S Naval Hospital, Oakland, California

The opinions expressed herein are those of the authors and are not necessarily those of the Navy Department.

The patient's father, mother and ten siblings were all living and well. There had been no known occurrence of diabetes or blood dyscrasias in the family.

On admission, the patient had no complaints, and physical examination revealed a well developed well nourished, young white male with no positive findings. The urine contained 4 plus sugar and the fasting blood sugar was 315 mg. per cent. The leukocyte count was 2,650 per cu. mm. with 1 per cent bands, 56 per cent segmented forms and 43 per cent lymphocytes.

The patient was placed on a diet of 2300 calories and the insulin dosage was regulated at 50 units regular and 30 units of protamine zinc insulin mixed in the same syringe and given daily before breakfast. Therapeutic agents given in an attempt to correct the leukopenia included the following: pentnucleotide 10 cc. intramuscularly daily April 18 to May 13, refined liver extract, 0.1 cc. intramuscularly daily May 24 to June 1, crude liver extract 1.0 cc. intramuscularly daily, June 2 to July 1, liver broth 500 cc. orally daily May 4 to May 18. None of these agents had any appreciable effect upon the number of neutrophils in the circulating blood.

On May 22, an abscessed tooth was extracted, penicillin being used prophylactically for several days. Two examinations disclosed normal vision and ocular fundi. Neither the spleen or the liver were palpated at repeated examinations of the abdomen. Roentgenograms of the chest and of the flat and long bones revealed no abnormalities. Gastric analysis using 100 cc. of 7 per cent alcohol as a stimulant showed no free acid in the fasting, the 30 minute and the 45 minute specimens but 16 and 20 degrees of free acid were

TABLE 1

Hour	Leukocytes	Neutrophilic		Lymphocytes	Eosinophils	Monocytes

2 00 PM	10,400	19	64	13	2	2
6 00	12,150	12	72	14		2

present in the 60 and the 75 minute specimens respectively. The subcutaneous injection of 0.7 cc. of 1:1000 solution of epinephrine hydrochloride produced a maximum rise in the blood sugar from 64 mg. per cent in the fasting specimen to 121 mg. per cent in the 90 minute specimen.

During the last month prior to surgery the prothrombin time, the bleeding time and the clotting time were found to be normal.

The patient's course was uneventful until October 15, 1946, when a splenectomy was performed by Capt. Harold F. Young, MC, U. S. Navy. The convalescence was uneventful and the patient was discharged from the Navy on December 24, 1946, because of the diabetes mellitus.

### BLOOD FINDINGS

1. *Cellular elements* The erythrocyte and the hemoglobin determinations revealed no appreciable deviation from normal throughout the hospital course. The leukocyte and the neutrophil counts performed in this hospital are shown in figure 1.

On the day of surgery, leukocyte and differential counts at frequent intervals revealed an immediate increase in the number of circulating neutrophils (table 1).

By the afternoon of the first postoperative day the leukocytes had dropped to 5,650 per cu. mm. and fluctuated only slightly thereafter. On the day of discharge, December 24, 1946, the leukocyte count was

FIG 1 BLOOD FINDINGS IN A CASE OF CHRONIC NEUTROPENIA

5,850 with 63 per cent segmented neutrophils, 33 per cent lymphocytes, 2 per cent eosinophils, and 4 per cent monocytes

Through the courtesy of Dr. M. M. Wintrobe of Salt Lake City, Utah, where the patient is now residing, the following values were obtained on February 4, 1947: 6,050,000 erythrocytes per cu. mm., 19.0 grams hemoglobin per 100 cc. of blood, 4,500 leukocytes per cu. mm., with a differential of 42 per cent segmented neutrophils, 38 per cent lymphocytes, 6 per cent eosinophils, and 14 per cent monocytes.

## 2. Mean erythrocyte determinations

Date	RBC	Hb	PCV	MCV	MCH	MCHC
6-21-46	5.08	14.5	53.0%	104	28.5	27.4
7-18-46	5.20	16.0	52.5	101	30.7	30.4
9-12-46	4.72	13.5	50.0	106	28.6	27.0
2-4-47	6.05	19.0	55.2	91	31.0	34.0

3. *Platelets* Numerous counts done by the indirect method of Fonio revealed an average concentration of 250,000 per cubic millimeter both pre- and postoperatively.

4. *Erythrocyte fragility* Determination by Sanford's method on two occasions revealed no significant deviation in the fragility of the patient's erythrocytes from that of the control.

5. *Cellular response following the injection of adrenalin* This procedure was done five days prior to splenectomy in an effort to determine if the spleen was a significant reservoir of blood. The dosage of adrenalin was 1.0 cc. of a 1:1,000 solution administered by the subcutaneous route. Blood pressure and pulse were recorded to ascertain the time of maximum response.

Time	Pulse	Blood pressure	Leukocytes per cu. mm.	Platelets per cu. mm.
Before injection	60	118/65	2,850	200,000
15 minutes after injection	62	122/68	8,100	240,000
30 minutes after injection	68	135/70	12,200	255,000
45 minutes after injection	65	125/65	6,300	204,000

The same procedure was repeated approximately one month following splenectomy as a control measure.

Time	Pulse	Blood pressure	Leukocytes per cu. mm.	Platelets per cu. mm.
Before injection	68	124/64	7,500	270,000
15 minutes after injection	80	146/66	9,750	400,000
30 minutes after injection	76	136/55	9,250	300,000
45 minutes after injection	70	135/56	9,000	340,000

6. *Sternal marrow study* Aspiration of the sternal marrow was performed on July 19, 1946, and the findings were as follows: Myeloblasts 1 per cent, myelocytes and metamyelocytes 9 per cent, erythrocytic band forms 17 per cent, neutrophilic segmented forms 3 per cent, eosinophils 1 per cent, lymphocytes 10 per cent, no pronormoblasts, normoblasts and macronormoblasts 39 per cent. The myeloid-erythroid ratio was 1:3. The production of granulocytes appeared to be somewhat decreased. A very few macrophages were found in the smears as resting forms or naked nuclei.

\* We gratefully acknowledge the assistance rendered by Dr. Harry Wexler of San Francisco and Commander John S. Shaver, MC, U. S. Navy, in the interpretation of the histology of the bone marrow and the spleen.

## PATHOLOGY

The spleen weighed 230 grams and measured  $14 \times 9 \times 5$  centimeters. The capsule was thin and translucent. Sections revealed a slightly congested, firm, reddish-tan pulp in which the Malpighian corpuscles were readily visible.

*Microscopic examination* The capsule and trabeculae of the spleen were of normal thickness and consisted of dense connective tissue and a scattering of smooth muscle cells. Histologically, the chief findings consisted of an increase in number and size of the lymphoid follicles, particularly the germinal centers and a moderate hyperplasia of the reticulo-endothelial elements lining the dilated sinusoids with enlargement of the splenic or Billroth's cords. The pulp was fairly devoid of erythrocytes but contained a moderately increased number of leukocytes of the polymorphonuclear type. The sinusoids were dilated and contained stagnated white blood cells of the granulocytic series. Only an occasional macrophage was found which contained identifiable nuclear fragments of the granulocytic series and this was considered minimal or within normal limits after comparison with normal splenic tissue from similar age groups. Many of the lining sinusoidal endothelial cells were laden with coarse granular brownish-black pigment, and an occasional degenerated red blood cell. No phagocytized white blood cells were found in these cells. The hyperplastic lymphoid follicles were unevenly distributed throughout the parenchymal tissue, and the sheathed arteries were not remarkable. Impression smears and supravital stains were not made.

## SUMMARY AND CONCLUSIONS

The case of a patient with chronic neutropenia without splenomegaly, but responding favorably to splenectomy is reported. The surgical procedure appeared to be indicated by the following: (1) exclusion of the extrinsic causes of neutropenia, (2) failure of response to the agents commonly employed to stimulate granulopoiesis, (3) demonstration of granulopoiesis in the sternal marrow, (4) increase in the circulating neutrophils following the parenteral administration of epinephrine, (5) the presence of coexisting diabetes with the potential hazard of infection.

The implication of the spleen as the main factor in the causation of the neutropenia in this case seems well established, although the specific mechanism is not apparent. There was no evidence of abnormal phagocytosis in the microscopic examination of the spleen.

## ACKNOWLEDGMENT

We wish to express appreciation to Captain Earl F. Evans, Medical Corps, U. S. Navy, for his assistance in the management of this case.

# LEUKEMOID REACTION DUE TO MIXED MALARIA INFECTION

## REPORT OF A CASE

By CAPTAIN JAMES A. RILEY, MC, AUS AND MAJOR GEORGE M. ROBINS, MC, AUS

**F**ALCIPARUM malaria has been rare in this country in returned soldiers and veterans because of the widespread use of atabrine as a suppressant in overseas areas. The suppressive dosages of this drug are believed to have been curative rather than merely suppressive for *P. falciparum* infections.<sup>1</sup> Recently at the Tilton General Hospital an instance of mixed malarial infection was seen in which both *P. vivax* and *P. falciparum* parasites were found in the peripheral blood smears (fig. 1). Another unusual feature in this case during the severe stage of the illness was a leukemoid picture in the peripheral blood and bone marrow. References to such reactions in the literature are scanty. Morin<sup>2</sup> reported a leukemoid reaction occurring in a young Greek woman who had relapsing malaria of eighteen months duration that had been inadequately treated before she came under his observation. He found the initial red blood cell and platelet counts to be normal and the white blood count to be 6,600 per cu. mm. with 73 per cent promyelocytes and 14.5 per cent myelocytes in the differential count. With quinine therapy the leukemoid blood picture returned to normal within two months. No bone marrow study was done. Schilling<sup>3</sup> states that acute tropical malaria may produce a marked shift to the left even to the extent of myelocytosis. Beregoff<sup>4</sup> found that malaria patients dying in coma showed low white blood cell counts and a marked shift to the left with neutropenia. Hill and Duncan<sup>5</sup> in their paper on leukemoid reactions refer briefly to the possibility of leukemoid reactions occurring in blackwater fever.

Because of the apparent rarity of leukemoid reactions in malaria and the infrequency of *falciparum* malaria in this country, the following case is reported.

## CASE REPORT

A 28 year old Negro male was admitted to Tilton General Hospital on Nov. 29, 1946 complaining of high fever, shaking chills, and profound weakness. He had been well until about November 1, 1946 when he was en route to the U. S. from Manila, Luzon, P. I. where he had been stationed for the previous nine months. On this date he developed chills, fever, headache, malaise, and weakness. Chills and fever occurred in paroxysms every other day for ten to fourteen days when all symptoms disappeared. The only treatment he received consisted of several large white pills of unknown composition each day. He arrived in the U. S. on November 18, 1946 and was sent from the debarkation point to the separation center and was home in Atlantic City by Nov. 22, 1946. On November 23, 1946 all his previous symptoms returned and again the chills and fever occurred approximately every second day. He was then admitted to the Tilton General Hospital. He stated that during his stay in the Philippine Islands he had never received any suppressive medication for malaria nor had he had malaria. As a child he had uncomplicated measles and chickenpox, and an appendectomy in 1934 with drainage from the wound for two weeks following surgery. The patient had lived in Richmond, Va. until 1934 when he moved to Atlantic City. There was no past history of episodes of chills, fever, or other illness. The family history was non-contributory.

On his admission the patient fairly well nourished and well developed, appeared acutely ill and exhibited evidence of weakness and weight loss. The rectal temperature was 96.4° F. A few tremors of the

From the Medical Service, Tilton General Hospital, Fort Dix, New Jersey.

upper limbs and head was present. All mucous membranes were quite pale. Examination of the eyes, ears, nose, mouth, and throat was negative. The ocular fundi were normal. The neck and thyroid gland were normal. No lymph nodes were palpably enlarged. The chest was symmetrical and the lungs were clear to auscultation and percussion. The pulse rate was 100 per minute and peripheral vessels were normal. The blood pressure was 110 systolic and 65 diastolic. The heart was not enlarged; the rhythm was regular, and a soft systolic apical murmur was present which was not transmitted and which varied somewhat with respiration. The abdomen was slightly distended and tympanitic, the liver and spleen were not palpably enlarged, but the splenic area was tender. Neurologic examination was normal except that the

FIG. 1.—(A) GAMETOCYTE *PLASMODIUM FALCIPARUM* (B) TROPHOZOITE, *PLASMODIUM VIVAX*  
(THICK SMEAR PERIPHERAL BLOOD)

patient showed some confusion as to the sequence of recent events and some retardation of cerebration. No other abnormalities were noted.

**Laboratory examinations.** The red and white blood counts on admission and during the hospital course of the patient are tabulated (table 1). On admission both thick and thin blood smears were negative for malarial parasites. The urine showed a specific gravity of 1.010 with a trace of albumin, no sugar, and an occasional white blood cell per high power field on microscopic examination. Two blood cultures were negative on December 14, 1946, and on January 10, 1947. No red blood cell sickling was demonstrated; the test being read at intervals up to twenty-four hours. Urinalysis on January 8, 1947, showed a specific gravity of 1.015, albumin and sugar negative, and 8-10 white blood cells, occasional granular

TABLE I—Blood Counts

FIG 2.—GRAPHIC TEMPERATURE CHART

casts and 0-2 red blood cells per high power field. A test for bile pigment was negative. Leucocytes were present in the urine in normal amounts.

On the patient's admission a diagnosis of malaria was made. However, this seemed improbable when two smears were negative for malarial parasites and the admission white blood count suggested aleukemic myelogenous leukemia. Therefore the patient was transfused with 500 cc of whole blood on November 30, 1946 and penicillin was given in 40,000 unit doses intramuscularly every three hours. Five hundred cubic centimeter blood transfusions were repeated on December 1, 1946, December 3, 1946 and January 5, 1947. On this therapy, together with 5 per cent glucose in saline intravenously, the patient's fever gradually receded and reached normal on December 3, 1946 (fig. 2). From December 6 to 15, 1946, the patient was afebrile and, except for weakness and malaise, free of symptoms.

On December 4, 1946, in an effort to clarify the blood picture and confirm the diagnosis of leukemia, a sternal bone marrow aspiration was done. The results of this and of a later bone marrow study are outlined in Table 2.

TABLE 2.—*Differential Counts of Sternal Bone Marrow Aspirations*

	Dec. 4 '46	Feb. 24 '47
%		
Neutrophils	3.6	18.0
Stab cells	0.0	3.2

Myeloblasts	7.9	1.2
Megakaryocytes	0.5	1.4
Erythroblasts	7.8	3.4
Normoblasts	12.4	19.6
Unidentified	3.8	1.2
Degenerated	0.0	4.8

The bone marrow study of December 4, 1946 showed a marked increase in the early forms of the neutrophilic series. Although the blast forms were not markedly increased, there was an increase in promyelocytes and myelocytes. Many degenerated cells were seen which were believed to be degenerating myelocytes and metamyelocytes. The smear was considered compatible with myelogenous leukemia.

After eight afebrile days the patient again began to have fever on December 16, 1946. The course of the temperature from then on is illustrated in figure 2. Each rise in temperature was accompanied by severe chill, marked headache and myalgia. On December 15, 1946 the physical findings were unchanged from those noted previously except that the spleen was palpable and quite tender. A blood smear taken on December 28, 1946, was found positive for *P. falciparum* and *P. vivax* (fig. 1). On December 30, 1946 treatment was started with atabrine in doses of 0.2 grams every six hours for 5 doses, then 0.1 gram three times a day for six days, and then 0.1 gram daily for the next thirty days. By January 4, 1947 the temperature was normal and the patient was greatly improved. From then on his convalescence was uncomplicated.

The previous bone marrow and peripheral blood smears were re-examined after the correct diagnosis

had been made, but again no malarial parasites were found. The final bone marrow study done on February 24, 1947, was normal. The severe anemia and the leukemoid reaction had disappeared.

The patient was discharged from the hospital on April 8, 1947, in good health. He was still well one month later.

### COMMENT

While it has been previously reported that immature cells of the granulocyte series occasionally appear in the peripheral blood during paroxysms of malaria, there is only one previous case report in the literature showing a marked shift to the left of the granulocyte series. No cases have been found in which bone marrow biopsies have been performed.

Because of the difficulties of diagnosis posed by a leukemoid picture in malaria and the rarity of this finding, this case is reported. It is possible that the increased hemolysis and the attending anemia are responsible in certain cases for sufficient bone marrow stimulation to cause this change.

### SUMMARY

A case of mixed malarial infection with a leukemoid blood picture is reported. The literature is reviewed.

## ERYTHROCYTES AND ERYTHROCYTIC DISEASE

ACTIVITY OF MICROBIAL ANIMAL PROTEIN FACTOR CONCENTRATES IN PERNICIOUS ANEMIA *E L R Stokstad A Page J Pierce A L Franklin T H Jukes R M Henle W Epstein and A D Welch* From the Lederle Laboratories Division American Cyanamid Company Pearl River, New York and the Departments of Medicine and Pharmacology, School of Medicine, Western Reserve University Cleveland Ohio *J Lab & Clin Med* 33 860-864 1948

These investigators have found that a nonmotile rod-shaped organism from hen feces when grown aerobically on simplified media produces appreciable quantities of the animal protein factor as indicated by assay with chicks on diets deficient in this factor. Since it is known that refined liver extracts produce a growth response in chicks deficient in the animal protein factor concentrates of the microbial animal protein factor were tested for anti pernicious anemia activity in two patients with pernicious anemia in relapse. The results indicate that the concentrates were active in inducing a hematopoietic response in such patients. Whether the active substance in the microbial concentrates is identical with the anti pernicious anemia factor or the recently isolated vitamin B<sub>12</sub> is not known. The answer to this will have to await chemical identification of the various substances. The possibility exists that factor X, the cow manure factor zoopherin the animal protein factor, the microbial animal protein factor vitamin B<sub>12</sub> and the anti pernicious anemia substances are all similar, identical or related compounds.

G E.C.

PRESENCE OF COBALT IN THE ANTI PERNICIOUS ANAEMIA FACTOR *E L Smith* From Glaxo Laboratories Ltd Greenford Middlesex England *Nature London* 162 144 1948

Examination of crystals of anti pernicious anemia factor has shown the presence of cobalt. If each molecule contains one atom of cobalt the molecular weight of the compound is about 1500. Allowance for loss on drying brings this in excellent agreement with that found on x ray crystallography (1550-1750). The higher value (3000) found by the diffusion method may be due to errors inherent in the method, the use of impure material in earlier experiments, or that association occurs in solution. Analytic figures indicate that the molecule contains three atoms of phosphorous. Reference is made to the fact that the Merck workers have found cobalt and phosphorous in their vitamin B<sub>12</sub>.

S T.C.

CONCENTRATION OF COBALT BY MICRO-ORGANISMS AND ITS RELATION TO COBALT DEFICIENCY IN SHEEP *J Tossie and Mitchell* From Rowett Research Institute, Bucksburn Aberdeenshire and Macaulay Institute for Soil Research Craigiebuckler Aberdeen Scotland *Nature London* 162 502-504 1948

Reference is made to previous work on cobalt as an essential factor in ruminant nutrition. Observations on three sheep with rumen fistulae are described. Sheep A was given a seeds hay diet (0.27 p.p.m. cobalt in dry matter). Sheep B and C bred originally on a cobalt deficient pasture were maintained on a hay diet containing only 0.07 p.p.m. cobalt. C was given 1 mg. added cobalt daily. After 6 weeks rumen contents were collected, fractionated, examined microscopically and for cobalt content. The data make it apparent that rumen micro-organisms concentrate cobalt from their external environment and that the cobalt concentration of the microbial population is related to cobalt content of the diet.

It is suggested that absorption of cobalt by the host may deprive micro-organisms of an essential factor, the host in turn being deprived of essential bacterial products, or if cobalt is an essential metabolite for the host alone, concentration in the micro-organisms may reduce its availability. Again host and alimentary micro-organisms may both require cobalt for metabolic activities, the competition being important on cobalt deficient diets.

Although this work is superficially remote from hematology the finding of cobalt in the crystalline anti-pernicious anemia factor indicates that it may be important in helping to elucidate the problem of megaloblastic anemias, especially those of intestinal origin. It may also link up with the experimental macrocytic anemia in rats (Watson et al. *Lancet* 2, 404, 1948) in which a gross change of microbial population of the intestine is probably produced.

STC

THE TREATMENT OF SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD WITH VITAMIN B<sub>12</sub>. T. D. Spies, R. E. Stone, S. Kartus and T. Aramborn. From the Department of Nutrition and Metabolism of Northwestern University at the Hillman Hospital, Birmingham, Alabama. *South M. J.* 41, 1030-1031, 1948.

The response to crystalline vitamin B<sub>12</sub> of 3 patients with pernicious anemia exhibiting acute neurologic manifestations is reported briefly. No data is presented other than that included in the one representative case report. The case is that of a 48 year old male with pernicious anemia who lapsed to treatment and presented a three weeks history of glossitis, weakness and inability to walk unsupported. Blood studies revealed a moderate slightly macrocytic anemia. Four parenteral injections of 25 micrograms each of vitamin B<sub>12</sub> were given at forty-eight hour intervals. Within the first forty-eight hours pain and tenderness of the legs and soreness of the tongue had disappeared and by the fourth day the patient could walk without support. Improvement in although not disappearance of abnormal neurologic signs (other than the return of a normal plantar response) was noted on the fifth day. A reticulocytosis of 14 per cent occurred on the fifth day followed by elevation of the red cells, white cells, platelets and hemoglobin (no figures given). Reference is made to the relief from neurologic symptoms noted in three previously reported cases following a single injection of 25 micrograms of vitamin B<sub>12</sub> (Postgrad M. 4, 89-95, 1948).

As the authors admit, insufficient time has elapsed to evaluate the effectiveness of vitamin B<sub>12</sub> as maintenance therapy for patients with pernicious anemia with or without neurologic complications. Certainly the experience with folic acid has shown that one must be extremely cautious in drawing conclusions from an initial neurologic improvement of several days.

CRYSTALLINE ANTI-PERNICIOUS-ANEMIA FACTOR IN TREATMENT OF TWO CASES OF TROPICAL MACROCYTIC ANEMIA. J. C. Patel. From Singhanee Hindu Hospital, Bombay, India. *Brit. M. J.* 2, 934-935, 1948.

Two cases of tropical macrocytic anemia occurring in Bombay showed a good response to single injections of 80 µg. each of Lester Smith's crystalline anti-pernicious anemia factor. This appears to be an interesting observation in view of previous suggestions that such cases are deficient in 'Wall's factor' rather than the anti-pernicious anemia factor.

STC

EXPERIMENTAL MACROCYTIC ANAEMIA IN THE RAT. G. M. Watson, D. G. Cameron and L. J. Wiles. From the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford, England. *Lancet* 2, 444, 1948.

Anemia resembling pernicious anemia sometimes develops in association with intestinal disease. This suggested a method for producing macrocytic anemia in rats. Two operations were devised. In the first

A the intestine was divided the lower part tied off and the upper part was anastomosed to the gut some 12 inches below the blind end. One hundred and eighteen rats survived operation and 21 developed macrocytic anemia six weeks to one year later. As anemia followed only when there was some stenosis at the anastomosis or dilatation of the loop operation B was devised. Here the lower part was anastomosed to the gut 12 inches above the division later modified to 3 inches. Peristalsis then filled the loop which always became dilated. Seventeen of 24 rats survived the 3 inch operation and 13 developed progressive anemia after an average of eight weeks.

The anemia is normo- or hyperchromic with an increase in red cell diameter and irregular reticulocytosis. The bone marrow shows an increase in proerythroblasts and basophil erythroblasts. Treatment with liver extract (total of 0.1 to 0.8 ml. Anahaemin) suggests that the anemia responds unless there are complicating infections. One rat injected with 15 mg. of folic acid also showed a good response. Further work is in progress to determine how specific are these responses to treatment.

Such experiments may provide the long sought test animal for the therapeutic potency of liver extracts although further advances in the research on crystalline anti-pernicious anemia factor may render this unnecessary. More important is the fact that the technique opens up a new field for the investigation of the pathogenesis of macrocytic anemia.

S.T.C.

**THE LIFE SPAN OF THE MEGALOCYTE AND THE HEMOLYTIC SYNDROME OF PERNICIOUS ANEMIA.** K. Singer, J. C. King and S. Robin. From the Department of Hematologic Research and the Department of Pediatric Research, Medical Research Institute, Michael Reese Hospital, Chicago, Illinois. *J. Lab. & Clin. Med.* 33: 1068-1076, 1948.

Determinations of the average life span of red cells from 4 patients with pernicious anemia in relapse were performed using the method of differential agglutination (Ashby technique). It was found that the survival time of the red cells when injected into normal individuals was markedly decreased (27 to 75 days). After adequate treatment, the life span of the cells from the pernicious anemia patients became normal. These observations, as the authors conclude, are evidence for the concept that pernicious anemia is a true hemolytic syndrome caused by an intracorporeal mechanism. The shortened life span of the cells would seem to account for the increased pigment production observed in this disease but it is difficult to correlate with the observations of London, Shemin and Rittenberg using labeled glycine which indicate that a considerable portion of the pigment production is derived from sources other than hemoglobin. It is likely that this problem is somewhat more complicated than it appears to be.

G.E.C.

**THE LIFE SPAN OF THE SICKLE CELL AND THE PATHOGENESIS OF SICKLE CELL ANEMIA.** K. Singer, S. Robin, J. C. King and R. N. Jefferson. From the Department of Hematologic Research and the Department of Pediatric Research, Medical Research Institute, Michael Reese Hospital and the Department of Pediatrics, Provident Hospital, Chicago, Illinois. *J. Lab. & Clin. Med.* 33: 975-984, 1948.

This paper deals with cross determinations of the survival time of sickle cells. Trait cells were transfused into patients with sickle cell anemia and anemia cells into healthy recipients displaying the sickle cell trait. It was found that the trait cells survived normally when transfused into patients with sickle cell anemia whereas the patient's own cells continued to be hemolyzed at a faster rate. Cells from patients with sickle cell anemia when transfused into trait carriers had a shortened life span with an average of about one fourth of the normal. Therefore the pathogenic principle operating in sickle cell anemia would appear to reside within the red cells themselves rather than in an extracorporeal mechanism. The authors conclude that the sickling process is by itself not a satisfactory explanation of the pathogenesis of the anemia. They speculate that sickle cell anemia develops because of an additional alteration in the cytoskeleton which is qualitatively different from the structural anomaly responsible for the sickling phenomenon.

G.E.C.

**A SIMPLE AND RAPID METHOD FOR DEMONSTRATING SICKLING OF THE RED BLOOD CELLS. THE USE OF REDUCING AGENTS.** G. A. Daland and M. B. Castle. From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital and the Department of Medicine, Harvard Medical School, Boston, Mass. *J. Lab. & Clin. Med.* 33: 1081-1088, 1948.

A simple and rapid method of producing sickling of the red blood cells in wet cover slip preparations of the blood of patients with sickle cell anemia is described. The principle on which the test is based is the production of reduced hemoglobin in the red cells by the addition of a reducing agent. In order to perform the test, a drop of a five fold aqueous dilution of Cevalin (approximateing a 2 per cent solution of buffered ascorbic acid and also containing 0.1 per cent sodium bisulfite) or a drop of 2 per cent sodium bisulfite  $\text{Na}_2\text{SO}_3$  is added to a small drop of the patient's blood on a glass microscope slide. After mixing, a cover slip is dropped on the preparation and excess blood is expressed by gentle pressure in order to produce a film of blood sufficiently thin to permit inspection of individual red cells under the high power objective of the microscope. With the diluted Cevalin solution, sickling of the blood usually appeared within an hour, and with the 2 per cent bisulfite solution it was often present within fifteen minutes at room temperature.

**DETERMINATION OF HAEMOGLOBIN V. PRECISION OF COLORIMETRIC METHODS** E. J. King, M. Gilchrist, J. D. P. Weston. From Postgraduate Medical School, London. R. Donaldson, R. B. Sisson. From the National Physical Laboratory, Teddington. R. G. Macfarlane, H. M. Jope, J. R. O'Brien. From the Radcliffe Infirmary, Oxford. J. M. Pitterson, D. H. Strangeways. From the University of Wales, Cardiff. *Lancet* 2, 563-566, 1948.

On blood samples from 11 male and 10 female subjects hemoglobin determinations were made by means of iron analyses, oxygen and carbon monoxide capacities. Various hemoglobin derivatives were tested by several types of photometer, photoelectric colorimeter and in one series of experiments with a Hilger medium quartz spectrograph. For visual instruments, the true reading was taken as the mean of 20-50 readings obtained by several observers. The readings were compared with the base line values obtained from the iron analyses and gasometric determinations respectively. Analysis of the results showed that the neutral grey wedge photometer (King, E. J., *Biochem. J.* 41, Suppl. 32, 1947) compared favorably with the standard photoelectric and visual instruments. The single cell photoelectric colorimeter proved more reliable than the two celled absorptiometer. Of the hemoglobin derivatives oxyhemoglobin and cyanhematin gave the least variable results.

Most hematologic laboratories now use photoelectric colorimeters for hemoglobin estimation but where such instruments are not available the grey wedge photometer seems to provide a simple and accurate instrument.

S. T. C.

**THE NATURE OF THE ANEMIA OF PREGNANCY IN THE RAT** C. F. Bond. From the Department of Zoology, Cornell University, Ithaca, New York. *Endocrinology* 43, 180-186, 1948.

The purpose of this work was to determine the nature of the anemia which accompanies pregnancy in the adult female rat of the Long Evans strain. Calculations were made on the total erythrocyte count, hematocrit, hemoglobin level, whole blood and plasma specific gravities and blood volume. Studies were made at three stages of pregnancy and on the second day postpartum. A significant decrease in whole blood and plasma specific gravities occurred during pregnancy, but the total blood volume increased. Calculations of the total circulating erythrocytes and hemoglobin in pregnant rats showed a sharp rise in both elements. The author concludes from this evidence that the anemia which accompanies pregnancy in the rat is due to a hemodilution.

R. C. C.

**ON THE GENESIS OF MEGALOBLASTIC BLOOD FORMATION** U. Haerfel. Medizin. Abteilung des Stadt-Krankenhauses Mannheim (Germany). *Klin. Wschr.* 1948, 8-12.

Using supravital examinations of bone marrow in pernicious anemia the author advances the theory of origin of megaloblasts from undifferentiated reticulum cells. He considers megaloblastic blood formation as a mesenchymatous process in contrast to the normal parenchymatous erythropoiesis. Furthermore, he points out the necessity of accepting a second factor in the genesis of megaloblasts. He considers this factor to be the loss of the mitotic heteroplastic properties of the cells and assumes this to be the effect of the absence of the antipernicious principle.

The peculiar megaloblastic nuclear structure is considered as the persistence of mesenchymatous nuclear properties.

C. V.

**LAWFUL MITOTIC STRUCTURE IN CYTOPLASM OF MATURING BLOOD CELLS** *H Wenderoth* I Medizin Universitätsklinik, Hamburg Eppendorf (Deutschland) *Klin Wschr* 1948 182-183

Studying the mitosis of megaloblasts gained from the bone marrow in pernicious anemia the author observed a singular granular structure of the nucleus, which he was able to stain with the Giemsa method and which is called paramitotic granulation because of its temporary appearance during mitosis. This granulation has been formerly described by Rohr (and others) who however, thought it identical with the basophilic stippling of the erythrocytes. The author believes that the phenomenon has to be differentiated from the former. Apart from the megaloblasts, the paramitotic granulation was also observed in normal maturing erythrocytes and leukocytes.

The author believes that the granulation belongs to other mesenchymal elements as well. The described structures are looked on as mitotic-formed agglomerations of the basophilic substance. A relation to the basophilic stippling of the erythrocytes is probable.

C.M.

**TOXIC DAMAGE TO ERYTHROCYTES FINDINGS WITH ELECTRON-OPTIC INVESTIGATIONS OF ERYTHROCYTES** *F Jung* *Klin Wschr* 1947, 459

Based on his electron-optic studies this author deduces that erythrocytes possess a genuine membrane made of protein and containing hemoglobin inside. The membrane is covered on its surface by a lipid layer. The inside is formed by a spongelike stroma made of protein. This latter is easily denatured, causing a change in permeability properties and leading to hemolysis. The author studied the influence of different salts and of hemolytic substances. He considers the Heinz bodies a sign of degeneration. They are composed of coagulated parts of the cells which are more easily stained and not really located in the inside of the cells. They have no relation to methemoglobin.

C.M.

## THROMBOEMBOLIC DISEASE

**THE EARLY RECOGNITION OF POST-OPERATIVE VENOUS THROMBOSIS INCREASED PROTHROMBIN ACTIVITY AS AN AID TO DIAGNOSIS** *E B Mahoney and R S Sandrock* From the Department of Surgery of the University of Rochester School of Medicine and Dentistry and Surgical Service of Strong Memorial and Rochester Municipal Hospitals Rochester New York. *Bull New York Acad Med* 24 636-650 1948

The prothrombin activity using Quick's one stage method was determined preoperatively and followed daily through the sixth postoperative day in 68 patients, most of whom were considered likely candidates for venous thrombosis. In nearly all 58 postoperative patients who did not develop thrombosis there was a progressive decrease in prothrombin activity during the first three days followed by a gradual return to normal about the sixth day. All of the 10 patients who developed thrombosis on the other hand showed a rise to above normal on either the second or third day. This hyperprothrombinemia was interpreted as evidence of impending thrombosis although the prothrombin activity was usually normal by the time thrombosis was clinically evident. No satisfactory explanation was offered for the fact that the hyperprothrombinemia was more uniformly apparent in the undiluted than in the diluted plasma determinations. The authors suggest this test as a practical method of early detection of postoperative thrombosis and as a basis for selection of patients to receive prophylactic anticoagulant therapy.

The pathogenesis, diagnosis and prevention of thrombo-embolism are discussed. In their comparison of the relative merits of prophylactic vein ligation and anticoagulants the authors present more convincing evidence for the latter.

The whole problem of the relation of prothrombin activity to the occurrence of intravascular thrombosis has yet to be defined although there are fewer conflicting reports on changes in prothrombin activity in postoperative than in nonsurgical patients (coronary thrombosis etc.) who develop thrombosis.

H.W.B.

**THE QUESTIONABLE IMPORTANCE OF BLOOD CHANGES IN CORONARY OCCLUSION** *J H B Hilsm W M Cameron E S Mills and S R Townsend* From the Departments of Medicine and Haematology Montreal General Hospital Montreal Quebec Canada. *Canad M A J* 59 447-452, 1948

It was concluded from a study of 31 cases of acute coronary occlusion that there were (1) no constant

changes in blood coagulability as measured by the Waugh Ruddick test (prothrombin time (diluted and undiluted plasma) or coagulation time, (2) no constant changes in the Waugh Ruddick test during prolonged bed rest, (3) no constant variation in plasma protein levels during convalescence (4) a high percentage of patients with prolonged circulation times due to shock and/or myocardial weakness and (5) that the variance in blood volume studies depended on the presence or absence of shock and/or cardiac failure

This study is of interest because of the present controversial issue of whether or not there is a current increase in clotting tendency to account for the appreciable incidence of thrombo-embolism in myocardial infarction. The prothrombin studies support the work of Cotlove and Vorzimer (*Ann Int Med* 24 648, 1946) but are at variance with that of others e.g., Peters et al (*J A M A* 130 398 1946). The findings of normal or decreased blood coagulability by the Waugh Ruddick test in 77.4 per cent of cases on admission with a low incidence (0.14 per cent) of increased clotting tendency during hospitalization in half of the group which did not receive dicumarol varies considerably from the results obtained by Ogura et al (*J Clin Investigation* 25 586 1946).

The answer to this problem awaits a more complete understanding of the clotting mechanism and its relation to intravascular thrombosis as well as a greater refinement and uniformity in our laboratory tests. However convincing evidence is accumulating in large series of cases to justify the cautious prophylactic use of dicumarol in patients with coronary occlusion.

H W B

**EFFECT OF HEPARIN AND DICUMAROL ON SLUDGE FORMATION** *H Lausman, W B Marin and C Tarter*  
From the Department of Surgery Northwestern University Medical School Chicago Illinois  
*Science* 108 283-284, 1948

The mesenteric vessels of dogs were studied using the Kniseley technique. Sludging was produced by venous occlusion. Dogs were divided into four groups. Group 1 Control dogs. After venous occlusion sludge formation developed followed by adherence of sludged masses to the endothelium of the vessels. This was followed by the piling up of more cells to the agglutinated mass until the vessel was finally completely occluded. The thrombosis remained in many vessels after the venous circulation had been released. Group 2 Heparin was given after the appearance of sludge formation. Group 3 Heparin was given before venous occlusion. Group 4 Dicumarol was given before occlusion. In the last three groups although sludge formation did occur no thrombosis developed in any animal.

R C C

**VENOUS THROMBOSIS AND PULMONARY EMBOLISM** *A W Allen and G A Donaldson*  
From the Surgical Service of the Massachusetts General Hospital, Boston Massachusetts *Bull New York Acad Med* 24 619-635, 1948

The specific prophylactic or therapeutic measures used in 2,600 postoperative patients some of whom received a combination of methods are evaluated. With few exceptions these were patients over the age of 30. Prophylactic treatment by small doses of dicumarol was given to 496 patients. None of these died of pulmonary embolism although there were two fatalities associated with hemorrhage. Four of 871 patients who had prophylactic bilateral superficial femoral vein interruption died subsequently of pulmonary embolism whereas in this particular group of patients deemed likely to develop thrombosis 37 deaths from embolism might have been expected had specific measures not been used. Treatment for 1,266 patients was by phlebotomy, thrombectomy and femoral vein interruptions after clinical evidence of thrombosis occurred. There were six deaths in this group from further emboli compared to an estimated sixty had therapy been withheld.

This paper includes a good discussion of the factors predisposing to venous thrombosis. Emphasis is laid on the fact that despite the progress made since the advent of specific measures in the prevention and treatment of thrombo-embolism a statistically significant percentage of patients still die from massive pulmonary embolism.

The authors do not share the general enthusiasm of many for the prophylactic use of dicumarol in postoperative patients. They stress its hazards and condemn its empiric use without adequate clinical and laboratory control. It is their opinion that vein ligation is the safer and more effective method in the older debilitated or very ill patient.

## HEMORRHAGIC DISEASE AND BLOOD COAGULATION

THROMBOGENIC PURPURA, THE FAILURE OF DIRECT BLOOD TRANSFUSION TO RAISE THE PLATELET LEVEL.

*J S Lawrence W N Valentini, and W S Adams* From the Departments of Medicine and Radiation Biology, The University of Rochester School of Medicine and Dentistry, Rochester New York. *J Lab & Clin Med* 33 1077-1081 1948

This work was undertaken with the purpose of determining if massive direct transfusions of blood given to patients with thrombopenia purpura would raise the level of circulating platelets significantly. A patient with aplastic anemia was given 1500 ml. of whole blood within a short period of time. A second patient was given approximately the same amount of blood on two different occasions. Theoretically this amount of blood should have raised the circulating platelet levels about 100 000 per cu. mm. However, in only one of the three experiments reported was a significant increase noted in the recipient, and in this case it was so small as to be of little practical importance. The reasons for the unsatisfactory results are not evident, but the results suggest that either the life span of platelets is exceedingly short or that they are unusually rapidly utilized in thrombocytopenic conditions.

G.E.C.

SURGERY IN HAEMOPHILIA. A CASE OF SPINAL SUBDURAL HAEMATOMA PRODUCING PARAPLEGIA.

*Schiller G Nilgün and O Budtz-Olsen* From the Nuffield Department of Surgery the Children's Department, and the Department of Pathology, Radcliffe Infirmary, Oxford. *England Lancet* 2 842-845 1948

A haemophilic boy of 16 months developed complete paralysis of both legs and retention of urine. Cisternal myelogram showed complete arrest of the opaque medium at T9. Laminectomy was performed and a large subdural clot removed successfully. Convalescence was complicated by secondary haemorrhage from the wound but general progress was excellent and a high degree of functional recovery took place. Throughout the course in hospital the prolonged clotting time was controlled by repeated small transfusions of fresh blood (62 in the 66 days in hospital). Larger volumes of blood were used only to replace blood lost.

This case illustrates a rare complication of haemophilia and also shows clearly that major surgery may be safely undertaken with adequate control by transfusion.

S.C.

STUDIES ON A PROTEOLYTIC ENZYME IN HUMAN PLASMA. III. SOME FACTORS CONTROLLING THE RATE OF FIBRINOLYSIS.

*O D Ratnoff* From the Department of Medicine The Johns Hopkins University School of Medicine, Baltimore Maryland. *J Exper Med* 88 401-416, 1948

The phenomenon of fibrinolysis has long been recognized and it is now well established that the blood contains both a proteolytic enzyme system and inhibitors of this system. However, the factors responsible for rapid clot dissolution under certain conditions remain a subject of controversy.

The author in this well controlled in vitro study of factors governing clot lysis, has observed certain interesting phenomena. Caseinolysis was used as a measure of fibrinolytic activity and his methods for the determination of proteolytic and inhibitory activity of plasma are described in detail. He was unable to demonstrate that there was any correlation between the clot lysis time of recalcified plasma clots and the amount of proteolytic activity either spontaneously developed or activated by chloroform or streptococcal filtrate in a globulin precipitated from the same plasma. Furthermore, a constant relationship between the inhibitory activity of fresh plasma serum or albumin against plasma proteolytic enzyme and clot lysis time could not be shown. Following the discovery that this inhibitory activity was unstable and decreased during incubation however, it was possible to correlate clot lysis time with the deterioration of inhibitory activity occurring during incubation of recalcified plasma at 37°C. This inhibitory activity decreased until a minimal stationary level was reached and fibrinolysis occurred. The nature of the labile component of the inhibitory activity of plasma is now under investigation.

The fundamental importance of the process of fibrinolysis and its relation to other physiologic processes involving the mechanism of blood coagulation, protein metabolism and the body's response to various stimuli have been appreciated only recently. The significance of such relationships are discussed in an excellent review of the subject by MacFarlane and Biggs (*Blood* 3: 1167, 1948).

H.W.B.

THE CONCENTRATION OF THE LABILE FACTOR OF THE PROTHROMBIN COMPLEX IN HUMAN DOG AND RABBIT BLOOD, ITS SIGNIFICANCE IN THE DETERMINATION OF PROTHROMBIN ACTIVITY. *A. J. Quick and M. Stefani*. From the Department of Biochemistry, Marquette University School of Medicine Milwaukee, Wisconsin. *J. Lab. & Clin. Med.* 33: 819-826, 1948.

A simple method for assaying the concentration of the labile factor of the prothrombin complex in blood is presented. This method is based on the principle that tricalcium phosphate when added to plasma removes components A and B of the prothrombin complex thus leaving fibrinogen and the labile factor as the only known plasma constituents playing a role in the process of clotting. On adding fresh plasma thus treated to stored human, dog or rabbit blood the prothrombin time was found to shorten strikingly. By determining the amount of plasma that had to be added to a fixed amount of stored plasma in order to reduce the prothrombin to an arbitrarily selected value (20 seconds) the relative concentration of the labile factor could be calculated. By this procedure it was found that the prothrombin time was reduced to a markedly shorter value when the labile factor was added to stored plasma than when added to fresh plasma, thus suggesting that something is elaborated in stored plasma which enhances the activity of the labile factor.

G.E.C.

A COAGULATION DEFECT PRODUCED BY NITROGEN MUSTARD. *T. R. Smith, L. O. Jacobson, C. L. Spurr, J. G. Allen, and M. H. Block*. From the Departments of Medicine and Surgery, the University of Chicago. *Chicago, Illinois Science* 107: 474, 1948.

Five patients were injected with nitrogen mustard (methyl-bis (beta-chloroethyl) amine hydrochloride) as follows: 2 were given 0.1 mg/kg on four successive days, 1 received the same dose and four injections at twelve hour intervals, 1 was given the same dose and four treatments at seven hour intervals and 1 was given 0.3 mg/kg two doses at six hour intervals. Within two weeks all 5 patients developed a moderate anemia, severe leukopenia, thrombocytopenia, prolonged bleeding time, cutaneous petechiae and ecchymoses. Coagulation time was prolonged. Intravenous injections of toluidine blue or protamine brought the coagulation time back to normal. The authors point out that nitrogen mustard treatment may induce serious or fatal complications due to the presence of an anticoagulant in the blood.

R.C.C.

MEASUREMENT OF THE ELECTRIC RESISTANCE OF HUMAN BLOOD. USE IN COAGULATION STUDIES AND CELL VOLUME DETERMINATIONS. *R. L. Rosenthal and C. W. Tobias*. From the Division of Medical Physics and the Department of Chemistry, University of California, Berkeley, California. *J. Lab. & Clin. Med.* 33: 1110-1122, 1948.

A method is described for the measurement of electric resistance of blood and other fluids. Lightly platinumized platinum electrodes were placed in tubes of blood. An audiofrequency oscillator was used to generate power. An oscilloscope was used instead of the conventional telephone bridge balance indicator. By means of a selector switch and parallel circuits six different samples could be studied at one time. All determinations were made in a constant temperature water bath set at 37°C.

Determination of resistance changes during the coagulation of blood make possible the determination of clotting time with elimination of inconsistencies caused by motion and offer a quantitative means for the study of clot retraction. By means of the ratio of blood resistance to plasma resistance the cell volume fraction of a sample of blood may be calculated. It was found that the centrifugation rate was 77 per cent too high (average) a value comparable to that obtained by Chapin and Ross by entirely different techniques (*Am. J. Physiol.* 137: 447, 1942).

G.E.C.

**STUDIES OF HEMOPHILIA I THE CONTROL OF HEMOPHILIA BY REPEATED INFUSIONS OF NORMAL HUMAN PLASMA** *B. Alexander and G. Landwehr* From the Medical Research Laboratories, Beth Israel Hospital and the Department of Medicine, Harvard Medical School, Boston, Mass. *J. A. M. A.* 138: 174-179, 1948

The authors report the prophylactic use of serial infusions of normal human plasma in hemophilia. It was found that the intravenous injection of 100 cc. of plasma into a hemophilic was capable of reducing the coagulation time of the blood to normal levels; the effect, however, began to disappear within a few (eight) hours. When 100 to 190 cc. of plasma was used, the effect was still present in twenty-four hours, was beginning to disappear in thirty-six hours, and was completely gone in three days. The use of larger amounts of plasma—up to 750 cc.—did not cause prolongation of the effect. It was further found that the administration of plasma intramuscularly was of little effect, 30 cc. of plasma having less of a coagulant power than 1 cc. given intravenously.

A schedule was therefore devised in which 100 to 180 cc. of reconstituted, freshly processed, frozen normal human plasma was administered intravenously three times a week to patients with hemophilia. Four patients with long histories of bleeding tendency and increased coagulation time were treated in this manner for from ten to twenty months. It was possible to maintain the coagulation times of these patients at high normal levels (15 to 20 minutes) and there was striking clinical improvement with elimination of serious hemorrhages. The only relapses occurred when, for various reasons, the schedule of plasma infusions was temporarily interrupted. The patients were able to work or go to school, indulge in sports, and even, in one case, undergo a surgical operation (tendon transplantation). There was no refractoriness to the plasma; on the other hand, there was no permanence of effect. The incidence of transfusion reactions was 1.2 per cent, and one patient developed mild serum hepatitis.

The clinical results in these cases are so striking as to endorse the authors' schedule of therapy as a beneficial and practical one at least until fractionation of normal plasma provides a consistently potent product for use in hemophilia.

SE

**INFLUENCE OF SULFONAMIDES ON BLOOD COAGULATION** *M. Kubias* From the City Hospital, Prague. *Čas. lékař. Čes.* 86: 291, 1947

Clinical observations seemed to indicate that the sulfonamides affect the blood coagulation. Therefore experiments were made to test this effect in patients treated for gonorrhea with various sulfa drugs. Blood coagulation, bleeding time, and osmotic resistance of red blood cells were systematically followed. In 10 patients treated in this way, the acceleration of blood coagulability was very marked; it appeared immediately following the first day of treatment and lasted for about six to nine days.

M.N.

**BLOOD PROTHROMBIN LEVEL IN PATIENTS SUFFERING FROM DISSEMINATED SCLEROSIS** *J. Lenf and L. Poldřek* From the Clinic of Nervous Diseases, Charles University, Prague. *Čas. lékař. Čes.* 86: 1569, 1947

Blood prothrombin has been determined in 53 patients suffering from disseminated sclerosis. 34 patients (65 per cent) were a little higher than normal in prothrombin content (over 120 per cent); some of these were very high (150 to 180 per cent). The arithmetical mean value of blood prothrombin was 120.6 per cent.

M.N.

## LEUKEMIA AND MALIGNANT LYMPHOMA

**THE HEMOGRAM IN MALIGNANT LYMPHOMATOSIS (HODGKIN'S DISEASE)** *J. Chester and G. Hemmiller* Medizinische Universitätsklinik, Lausanne (Switzerland). *Praxis* 24: 440-442, 1948

The authors studied the hemogram of 56 cases of Hodgkin's disease. The leukocyte count was subject to important fluctuations and specially in the terminal phase of the disease, leukopenia was more common than leukocytosis.

Lymphopenia was the most frequent symptom; the authors give figures of 60 per cent initially and 90 per cent terminally in the illness. Eosinophilia was less frequent (12 per cent); the same was so for the frequently described monocytosis.

Anemia was seldom seen at the beginning and always developed sooner or later during the course of the disease.

C.M.

**STUDIES IN HODGKIN'S SYNDROME VII NITROGEN MUSTARD THERAPY** R. P. Zares C. A. Dean and H. A. Hoster From the Department of Medicine and the Division of Cancer Research Ohio State University, Columbus, Ohio *J. Lab. & Clin. Med.* 33: 1002-1018, 1948

Thirty-one cases of Hodgkin's disease were treated with a total of 44 courses of methyl bis( $\beta$ -chloroethyl) amine hydrochloride. Beneficial results were observed in 20 patients receiving twenty-four courses. Indirectly, 3 other patients benefited through an apparent resensitization to roentgen rays. Improvement was characterized in most instances by an immediate disappearance of fever, itching and pain. Brownish pigmentation of the skin was observed to decrease in several cases as did Hodgkin's skin lesions, splenomegaly, hepatomegaly and adenopathy. A regeneration of lymphocytes and a return of the monocyte lymphocyte ratio toward normal was the most consistent laboratory finding associated with a clinical remission. Bone marrow hypoplasia proceeding to aplasia and followed in every instance by complete regeneration to the previous level and in some cases to a more normal level within a few weeks after therapy was observed.

**NITROGEN MUSTARDS IN FOWL LEUCOSIS** E. P. Johnson From the Section of Animal Pathology Virginia Agricultural Experimental Station Blacksburg Virginia *Science* 107: 40-42, 1948

This experiment was performed to determine the effects of nitrogen mustards on the leukosis of fowls. Chicks of 1 to 2 weeks of age were injected with the Belville strain A leukosis virus either intravenously or intraperitoneally. After the leukosis had become established (four to six weeks) chicks were treated with  $\text{HN}_2$  or  $\text{HN}_3$ . Optimal dose of  $\text{HN}_2$  was found to be 1.0 mg/Kg. for  $\text{HN}_2$ , 2.0 mg/Kg. Of 14 birds treated with  $\text{HN}_2$ , 2 made clinical recoveries lasting from three to six months. Of 19 birds treated with  $\text{HN}_3$ , 11 made complete recoveries. With treatment early in the disease the recovery is greater. This work indicates that two nitrogen mustards have a profound action upon the immature cells called hemocytoblasts, retard the mitotic activity both of the blood and the bone marrow, and have a lethal effect upon the virus which causes the disease as indicated by the failure of blood drawn from the treated animals to infect a normal host.

R. C. C.

**PULMONARY EDEMA IN LEUKEMIC MICE FOLLOWING TREATMENT WITH URETHANE** W. W. Winchester and G. M. Higgins From the Division of Experimental Medicine Mayo Foundation Rochester Minnesota *Science* 107: 568-569, 1948

This paper was a study on the effects of urethane on pulmonary capillaries in the mouse. The mice used were F<sub>1</sub>NH hybrids transplanted with myelogenous leukemia. Urethane was administered intraperitoneally after the leukocyte counts were in the neighborhood of 200,000 cells per cu. mm. Doses of urethane varied from 0.5 mg./Gm. daily to 1.0 mg./Gm. daily. Pulmonary edema was present in all treated animals. Giving graded doses produced edema in all cases in which the dose of urethane was sufficient to have an effect on the leukemia. If death did not result from the edema, a subsequent development of pneumonia did produce death. Although the edema was restricted to the lungs, evidence was found of capillary damage in other regions of the body. The authors point out the toxic effects of urethane when used over a long period of time.

**URETHANE INDUCED LYMPHOPENIA IN NORMAL AND ADRENALECTOMIZED RATS** A. Dwyer and E. D. Rabin From the Department of Physiology George Washington University, Washington D. C. *Endocrinology* 42: 320-325, 1948

Urethane has been used in the treatment of leukemia. This substance has been reported as inducing a lymphopenia as well as other effects. Urethane treatment also induces an adrenal hypertrophy. In view of the work of Dougherty and White where a lymphopenia was induced by adrenal cortical extracts, this work was done to determine whether urethane induces the lymphopenia via the adrenal cortex. Adult male rats of the Sprague Dawley strain were used.

A leukopenia and an absolute lymphopenia were induced by urethane by these authors in both normal and adrenalectomized rats. The adrenals would therefore not seem to be the factor which induces lymphopenia under urethane treatment. The authors discuss the theory that urethane acts as a bone marrow poison.

THE CHANGE IN THE LEUCOCYTIC FORMULA BY THE LEUCOCYTOSIS-PROMOTING FACTOR OF EXUDATES IN EXPERIMENTAL LEUCEMIA *V Menkin* From the Agnes Barr Foundation for Cancer Research Temple University School of Medicine, Philadelphia, Pennsylvania *Science* 107 546-547 1948

Leukemia was induced in mice by injections of leukemic material. A few days to a few weeks later the mice were injected subcutaneously with 1.2 mg. of leukocytosis-promoting factor (obtained from canine exudates as previously described by the author). Injections were daily at first and, after several weeks, three times per week. This material induced a shift in the differential leukocyte formula with a rise in the percentage of mature polymorphonuclear leukocytes. Several children with leukemia were injected with this material. The only positive effect was a frequent drop in the total leukocyte level. R.C.C.

REGRESSION OF LYMPHOSARCOMA PRODUCED BY INTRAPERITONEAL ADMINISTRATION OF 95% ETHYL ALCOHOL. *A D Bass and M L H Freeman* From the department of Pharmacology Syracuse University College of Medicine Syracuse New York. *Science* 107 114-115, 1948

This experiment was performed in an attempt to determine whether the effects of alcohol on lymphosarcoma were due to a direct effect or to effects mediated by the adrenal cortex. C<sub>3</sub>H mice bearing 6C<sub>3</sub>HED tumors were used. One group of mice was treated with 19 per cent ethyl alcohol and another group was treated with various amounts of 95 per cent alcohol. The 19 per cent alcohol produced no toxic symptoms and no tumor regression, while the 95 per cent alcohol did produce toxic symptoms and showed a definite tumor regression. Diffuse cell necrosis was seen in the tumors treated with the 95 per cent alcohol. The results did not answer the original question as to whether the adrenal cortex was involved. The authors suggest that the results obtained were not due to the alcohol itself but were due to the toxic effects obtained. R.C.C.

SYSTEMIC ALEUKEMIC RETICULOENDOTHELIOSIS (LETTERER-SIWE DISEASE) *C Varga, M N Rubter and A G DeSanctis* From the Department of Pediatrics and the Department of Pathology New York Post Graduate Medical School and Hospital New York. *Am J Dis Child* 75 376-384 1948

Three cases of systemic aleukemic nonlipid reticuloendotheliosis are reported with a brief discussion of the disease. The usually accepted criteria of this disease are (1) its occurrence, neither hereditary nor familial, in infants and young children, of unknown etiology and fatal prognosis, (2) hepatosplenomegaly, (3) generalized lymphadenopathy, (4) hemorrhagic diathesis, (5) localized skeletal changes or tumors, (6) progressive secondary anemia, usually with a normal leukocyte count, (7) general hyperplasia of the cells of the reticulo-endothelial system which may assume focal tumor-like proliferation, and (8) an acute onset unrelated to infections. The authors take issue with this last criterion as their cases, like many others reported in the literature, were associated with, although not necessarily caused by, infection. Emphasis was also placed on the presence of cutaneous lesions similar to seborrheic dermatitis which so frequently occur in the systemic reticulo-endothelial diseases.

Certain authors, including Siwe, have made a distinction between this disease and so-called infectious reticuloendotheliosis, which in all other respects appear to be similar. The very frequency of infections in young children as well as those occurring coincidentally in malignant disease make such a distinction extremely tenuous. One wonders about the precise relationship of this disease to Schüller-Christian disease, leukemic reticuloendotheliosis, reticulum cell sarcoma, etc., and whether it should be rightly considered a separate disease entity. Certainly our whole concept of the reticulo-endothelial disorders is confusing and badly in need of clarification. H W B

LYMPHOCYTE DISCHARGE FROM THE ISOLATED RABBIT SPLEEN BY ADRENAL CORTICAL EXTRACT *O Habtin* From the Worcester Foundation for Experimental Biology Shrewsbury, Mass. and the Department of Physiology Tufts Medical College Boston, Mass. *Endocrinology* 42 285-306, 1948

The purpose of this experiment was to determine the effect of adrenal cortical extract (ACE) on the lymphocyte content of the spleen under *in vitro* conditions. Rabbits served as the source of the spleens and the blood. A perfusion apparatus was used, the details of which are given. ACE administered to the isolated rabbit spleen under conditions of constant pressure and bathed by whole blood produced a

significant rise in the lymphocyte content of the blood. This rise occurred rapidly (15 minutes). The lymphocytes then dropped below normal levels. This secondary decrease in the circulating lymphocytes appears to be due to accelerated lymphocyte breakdown by the spleen, in the presence of ACE. These reactions to ACE were not dependent on changes in pressure or splenic blood flow. They could not be elicited with the thymus, lung or liver. Glucose, epinephrine, desoxycorticosterone acetate and estradiol propionate had no effect on the circulating lymphocytes.

R.C.C.

**SOLENIC LYMPHOCYTE DISCHARGE INDUCED BY ADRENAL CORTICAL HORMONES UNDER IN VIVO CONDITIONS**  
D. Stone and O. Hechter. From the Worcester Foundation for Experimental Biology, Shrewsbury, Mass., and the Department of Physiology, Tufts Medical School, Boston, Mass. *Endocrinology* 42: 307-314, 1948.

In a previous paper it was noted that adrenal cortical extract (ACE) produced a discharge of lymphocytes into the circulation from the spleen under *in vitro* conditions. This work was done to study the spleen under *in vivo* conditions. Rats were used for the experiment and a stress was obtained by making the rats swim. A lymphocytosis resulted from this stress in normal animals. This rise was significantly decreased by adrenalectomy or splenectomy. Injections of ACE to adrenalectomized swimming rats produced a lymphocytosis. ACE injections had no effect on adrenalectomized splenectomized swimming rats. Desoxycorticosterone acetate had no effect. ACE, then, would seem to induce lymphocyte discharge from the spleen under *in vivo* conditions as well as under *in vitro* conditions. This work is interesting when compared to the lymphopenia obtained by ACE in previous reports by Dougherty and White. Is the breakdown of the lymphocyte in lymph nodes greater than the discharge from the spleen when animals are injected with ACE?

**LYMPHOPENIA FOLLOWING ELECTRICALLY INDUCED CONVULSIONS IN MALE PSYCHOTIC PATIENTS. IV**  
P. Mikkelsen and T. T. Hutchins. From the United States Veteran Administration Hospital, American Lake, Washington. *Endocrinology* 42: 394-398, 1948.

The object of this experiment was to determine if the stress of an electrically induced convulsion would produce a lymphopenia in psychotic patients. A significant lymphopenia was found in the third hour following both the grand mal and petit mal reactions. The relation of these results to the lymphopenia found after other stresses and after injections of adrenal cortical extract or adrenocorticotrophic hormone are discussed.

## IMMUNOHEMATOLOGY

**PRELIMINARY NOTE ON INFLUENCE OF HETERO SPECIFIC IMMUNIZATION ON PRODUCTION OF RH ANTIBODIES**  
J. J. van Loghem. Centraal Laboratorium van den Bloedtransfusie dienst, Binnengasthuis, Amsterdam. *Brit. M. J.*, 2: 316-318, 1948.

Volunteers were given repeated intravenous injections of red cells in an attempt to induce anti Rh agglutinins. When, after 15 to 41 injections, no antibodies were found mixed typhoid, paratyphoid vaccines were given simultaneously.

The relatively weak antigens C and E were used. Rh antibodies appeared in 4 of 17 volunteers, 2 of these only after vaccine injections. One of the others showed a striking increase in titer after the vaccine. In general, only those who showed a clinical response to the vaccines and who produced antibodies to nearly all the injected typhoid antigens showed a satisfactory Rh antibody response.

If this observation can be confirmed on a larger scale the technique should prove most useful both for producing anti sera and as the author suggests, for screening for potentially good antibody producers.

**GENETIC TRANSMISSION OF TWO RARE BLOOD GROUP GENES**  
A. S. Wiener. Jewish Hospital, Brooklyn, N. Y. *Nature*, London 162: 735, 1948.

This note records the phenotypes and genotypes of four families, three of whom show transmission of the gene R<sup>s</sup> and one the extremely rare r<sup>s</sup>.

S.T.C.

**INTRAGROUP INCOMPATIBILITY WITH RESPECT TO THE H<sub>r</sub> BLOOD FACTORS AS A CAUSE OF MINOR HEMOLYTIC TRANSFUSION REACTIONS** *A S Wiener* From the Blood Transfusion Division of the Jewish Hospital of Brooklyn and the Serological Laboratory of the Office of the Chief Medical Examiner New York New York *J Lab & Clin Med* 33 985-997 1948

At the author's institution, the frequency of post transfusion febrile reactions has been reduced from 7.9 per cent in 1936 to only 1.2 per cent in 1947 as a result of the perfection of methods of eliminating pyrogenic materials from blood transfusion apparatus. This virtual elimination of pyrogenic reactions has served to make more prominent mild hemolytic reactions occurring in Rh positive patients as a result of H<sub>r</sub> sensitization by repeated transfusions given over a long period of time. In a series of 23 Rh positive patients having febrile reactions and at the same time showing evidence of posttransfusion hemolysis 17 were H<sub>r</sub> negative. Among 10 patients with febrile reactions but without evidence of hemolysis one was H<sub>r</sub> negative. The author suggests that one should investigate every febrile reaction for evidence of hemolysis. If hemolysis has occurred even though the patient is Rh positive, H<sub>r</sub> tests should be done and if the patient is found to be H<sub>r</sub> negative, only H<sub>r</sub>-negative blood of a compatible blood group should be used for future transfusions. If Rh negative patients have reactions despite transfusions of type rh blood, one should search for other sensitizations, particularly against the M factor.

G.E.C.

**SPECIFIC SERUM AGGLOUTINATION OF ERYTHROCYTES SENSITIZED WITH EXTRACTS OF TUBERCLE BACILLI** *G Middlebrook and R J Dubos* From the Laboratories of the Rockefeller Institute for Medical Research New York, New York *J Exper Med* 88 521-528, 1948

Sheep's erythrocytes sensitized with extracts of human tubercle bacilli or products of their culture filtrate were agglutinated by sera of rabbits previously injected with BCG and by sera of patients with active pulmonary tuberculosis. At least one material capable of sensitizing the red cells was shown to be heat stable and present in the polysaccharide fraction of the tubercle bacillus. Evidence for the specificity of this hemagglutination was obtained from the negative or insignificant reactions observed when the sensitized red cells were tested against sera of experimental animals immunized with other bacteria and against sera of nontuberculous individuals. It was of particular interest that there was no cross-reaction with Wassermann positive sera.

Inhibition of the specific hemagglutination reaction was accomplished by adding the soluble reactive antigen to the serum before the red cells were introduced into the system. Utilization of both the inhibition test and the agglutination test permitted the detection and quantitation of small amounts of the sensitizing antigen.

The authors have suggested the possibility that this method may be of aid in the detection of a specific antigen circulating in vivo and that there may be even some correlation between the degree of activity of tuberculosis and the titer of the patient's serum in the hemagglutination test.

### EXPERIMENTAL PRODUCTION OF A NUTRITIONAL MACROCYTIC ANEMIA IN SWINE

By G E CARTWRIGHT, M D, BETTY TATTING, B S, HELEN ASHENBRUCKER, B A,  
AND M M WINTROBE, M D, Ph D

THE PURPOSE of this paper is to describe the experimental production of a macrocytic anemia in swine made deficient in pteroylglutamic acid. This subject is of interest because of the morphologic resemblance of the experimental anemia to pernicious and related macrocytic anemias, and because it is known that the hematologic manifestations of these anemias respond to pteroylglutamic acid. A preliminary report of this work has appeared.<sup>1</sup>

#### REVIEW OF THE LITERATURE

Since the contributions of Minot and Murphy in 1927<sup>2</sup> and of Castle in 1929<sup>3</sup> concerning the etiology of pernicious anemia, many attempts have been made to produce macrocytic anemia in animals by a variety of different approaches. However, the entire pernicious anemia syndrome has not yet been produced in the experimental animal.

Several investigators have reported the production of macrocytic anemia in swine. Miller and Rhoads<sup>4</sup> as early as 1935 fed swine a canine black-tongue producing diet and observed a symptom complex which included anemia, lesions of the oral mucous membranes, gastric achlorhydria, diarrhea and motor weakness of the extremities. The disorder was thought to be associated with a loss of the anti-pernicious anemia activity of the gastric secretion and liver. Remissions of the anemia and amelioration of symptoms were induced by the administration of liver extract. Contrary to their claim, however, the anemia was not actually macrocytic. The average mean corpuscular volume in the animals with macrocytic anemia was reported to be 59.5 c. The mean corpuscular volume in normal swine is about  $56 \pm 5.16$  cu.<sup>1</sup> Furthermore, intermittent periods of achlorhydria may be observed in normal swine.<sup>5</sup>

Smith, Reiser and Harrell<sup>6</sup> observed a macrocytic anemia in weanling pigs on a prolonged partial deficiency of the vitamin B complex but spontaneous cure of the anemia ensued while the pigs remained on the same diet and without treatment. The diet used was a modification of the Goldberger black-tongue producing diet.

From the Department of Medicine, College of Medicine, University of Utah, Salt Lake City, Utah.  
Aided by a grant from the United States Public Health Service and the Upjohn Company, Kalamazoo, Michigan.

and was almost identical to that used by Miller and Rhoads.<sup>4</sup> The mean corpuscular volumes reached 74 to 97  $\mu$ . The inclusion of 10 per cent brewer's yeast in the diet protected the animals. McGowan and Sinclair<sup>7</sup> found that young pigs kept on a ration of corn, fish meal and "draff" became ill with anemia and jaundice and liver damage were observed. The anemia was described as macrocytic and the femoral marrow was red and cellular. Reticulocyte increases occurred following the administration of raw liver, the anemia disappeared and the bone marrow became normal. Lawrason and Cronkite<sup>8</sup> observed a macrocytic anemia and achlorhydria in two pigs exposed to atom bomb ionizing radiation at Bikini. In one animal the bone marrow was hyperplastic and megaloblastic-like. The relation of these instances of anemia in experimental animals to nutritional deficiency is not clear.

Welch, Heinle and colleagues<sup>9-11</sup> have reported the production of macrocytic anemia with megaloblastic hyperplasia of the bone marrow in pigs maintained on a highly purified diet essentially free of extrinsic factor and to which sulfasuxidine and a folic acid antagonist were added. One of the animals responded to the administration of crude sodium caseinate together with a 95 per cent ethanol extract of crude casein and normal human gastric juice. This animal later relapsed and was treated successfully with a single injection of 15 units of liver extract. A second animal responded rapidly to four daily intramuscular injections of 10 mg. of pteroyl glutamic acid. A third pig became critically ill and was successfully treated with a combination of purified liver extract, pteroylglutamic acid and niacinamide. These investigators concluded that purified liver extract is effective in correcting the anemia initially but found that relapses developing after liver-induced remissions were refractory to liver extract.<sup>11</sup> Extract prepared from the liver of a pig raised on the purified casein diet and given pteroylglutamic acid was hemopoietically inactive when assayed in a patient with pernicious anemia. An extract from the liver of the same animal after a month on the same diet, except that crude casein containing extrinsic factor replaced the purified casein, was active when so assayed. An extract prepared from normal pig liver was even more active. It was concluded that pteroylglutamic acid can elicit a complete hematopoietic response in pigs on a purified diet poor in extrinsic factor.<sup>11</sup> Our own studies in swine<sup>1</sup> have been alluded to already and will be discussed more fully later.

In monkeys, Wills reported<sup>12-15</sup> the production of a severe macrocytic anemia with a megaloblastic bone marrow. The animals were given a diet similar to that in common use among the poorer class of Mohammedans in Bombay, where nutritional macrocytic anemia is common. It consisted of polished rice, margarine, salt, iron, white bread, cod liver oil, and either tomatoes or carrots. The anemia responded rapidly following the administration of either marmite or Campolon but purified anti-pernicious liver extracts were ineffective. Bartonella infections were not present.

The earlier work in dogs fed a modified Goldberger black-tongue producing diet was inconclusive.<sup>16</sup> Several of the dogs had been splenectomized and it was later demonstrated that the anemia was complicated by Bartonella infection and that such an infection was capable of itself producing a severe anemia.<sup>17</sup> Later a rela-

relationship between nicotinic acid deficiency and the development of macrocytic anemia was suggested by the work of Handler and Featherston.<sup>18</sup> Dogs fed three different types of diet deficient in nicotinic acid developed severe macrocytic anemia. A sharp reticulocyte response and subsequent elevation of the red cell count and hemoglobin followed the administration of nicotinic acid but not when purified liver extract was given. More recently Ruegamer, Brickson, Torbet and Elvehjem<sup>19</sup> observed that when young growing dogs were fed a niacin-deficient purified ration containing 1 per cent sulfasuxidine, weight loss and signs of black-tongue developed. Small doses of niacin were only partially effective in combating the loss of weight. Pteroylglutamic acid helped to produce a more consistent response to niacin but had no apparent effect on the macrocytic anemia which appeared and became progressively more severe. Diarrhea was present and in the most deficient animals a pronounced, flaccid type of paralysis was observed. As little as 0.05 ml. of purified liver extract (20 units/ml) was effective in bringing about a complete remission of the anemia. Bone marrow studies were not mentioned. This work would seem to be of considerable importance if it can be confirmed since it represents the only liver extract responsive, macrocytic anemia associated with neurological symptoms to be reported to date in experimental animals. The administration of choline<sup>20</sup> or acetylcholine<sup>21</sup> has been claimed by Davis to produce a macrocytic anemia in dogs but this has not been confirmed.<sup>22</sup>

Wills<sup>12</sup> produced macrocytic anemia in rats but found that the anemia was due to Bartonella infection. Watson, Cameron and Wits<sup>23</sup> have reported that the formation of a blind intestinal loop in rats leads to the development of a macrocytic anemia which responds to purified liver extract. The bone marrow contained increased numbers of proerythroblasts and basophilic erythroblasts. A striking difference between this anemia and that seen in nutritional macrocytic anemia and in pernicious anemia is the fact that marked reticulocytosis (10 to 40 per cent) was present in the rats prior to therapy.

It has been reported that in some instances a deficiency of copper in sheep<sup>24</sup> and cattle<sup>25</sup> is associated with a macrocytic anemia but detailed morphologic studies have not been done and this work needs confirmation.

Pteroylglutamic acid deficiency in the rat<sup>6, 23</sup> is associated with severe normocytic anemia, granulocytopenia, lymphopenia and thrombocytopenia. However, such a deficiency in the chick has been described as leading to the development of macrocytic anemia<sup>26</sup> and the mean corpuscular volume has been reported to be increased from the normal of 137  $\mu$  to 161  $\mu$ . The anemia is accompanied by severe leukopenia, due mainly to lymphopenia, the absolute numbers of neutrophils being maintained. The thrombocytes also diminish in number. In none of these species has the anemia responded to purified liver extract therapy.<sup>6, 23</sup>

The entire stomach of various species of animals including the dog, cat, rat, pig and monkey has been removed by a number of investigators. This approach has not resulted in the production of macrocytic anemia in any species.<sup>27</sup> Petri and his group<sup>28</sup> in a large series of experiments extending over a period of nearly twenty years have failed to produce macrocytic anemia in either the dog or the pig. They

have observed, however, that total gastrectomy in swine leads to the complete disappearance of the anti-pernicious anemia substance in the liver and that nicotinic acid therapy subsequent to the resection can prevent this loss<sup>23</sup>

### EXPERIMENTAL PROCEDURE

Including the four animals described in the preliminary report,<sup>1</sup> a total of 32 weanling Chester White pigs 21 to 28 days of age were used in this study. The animals were housed in individual cages and were fed the purified diet from the day they were received which was also the day of weaning.

Two types of basal diet were fed, a 10 per cent and a 26 per cent protein diet the compositions of which were as follows

	per cent	per cent
Casein	26.1	10.0
Sucrose	57.7	73.8
Lard	11.0	11.0
Salt mixture <sup>24</sup>	5.2	5.2

Two types of casein were used in different animals. Sheffield's New Process (crude) casein and Sheffield's alcohol-extracted (purified) casein. The latter was prepared from Sheffield's high nitrogen casein<sup>25</sup> by presoaking for 18 hours with cold 98 per cent methanol at pH 6 followed by a continuous 24 hour extraction with hot methanol. The extracted casein was then tray dried to remove the residual methanol.

It has been demonstrated previously in this laboratory by assay in patients with pernicious anemia to relapse that the Sheffield New Process (crude) casein contains significant amounts of extrinsic factor activity.<sup>1</sup> The Sheffield alcohol-extracted (purified) casein has been assayed in a similar manner for extrinsic factor activity. The procedure of assay was as follows. The patient was hospitalized and during the assay periods liver, meat, meat products, milk and poultry were excluded from the diet. Bread, cereals, sugar, fats, vegetables and fruits were permitted in the amounts desired. Daily for ten days 50 grams of the casein to be assayed were incubated at 37°C for two hours with 150 to 200 ml of normal human gastric juice at pH 2.5 to 3.5. The incubation mixture was then strained through cheese cloth, the filtrate was neutralized to pH 5.0 and administered immediately to the patient. The results are shown in figure 1. The purified casein in the quantity given contained insignificant amounts of extrinsic factor activity whereas the same quantity of crude casein apparently carried an amount adequate to give a significant reticulocytosis and rise in volume of packed red cells. Following this response the administration of one U.S.P. unit of purified liver extract daily for ten days did not produce a further reticulocytosis.

Depending upon the type and amount of casein in the basal diet the animals were divided into four groups as follows:

Group A—Crude casein 10 per cent

Group B—Crude casein 26 per cent

Group C—Purified casein 10 per cent

Group D—Purified casein 10 per cent plus 15 U.S.P. units of purified liver extract (61039 Parke Davis 15 U.S.P. units per ml) administered intramuscularly every 15 days from the beginning of the experiment.

The basal diet was fed in amounts of 365 grams (152 calories) per kilogram of body weight per pig per day. Sulfasuxidine was added to the basal diet of all animals in amounts of 2.0 per cent. All animals were given a crude methyl folic acid antagonist prepared† by allowing 2.45 triamino-6-hydroxyprimidine and p-amino benzoyl L (+)-glutamic acid to react with 2,3-dibromobutyraldehyde.<sup>26, 27</sup> This antagonist was administered daily either in capsules (0.06 Gm per kilogram of body weight) or added to the diet (0.2 per cent). Natola (Parke, Davis 5500 units of vitamin A, 11000 units of vitamin D per gram) 0.056 gram per kilogram of body weight per week supplemented the basal diet. Vitamins

\* Prepared by heating freshly separated fat free milk to 110–115°F and precipitating the casein with dilute muriatic acid at pH 4.5–4.6. The casein is then repeatedly washed to reduce the free acid and mineral constituents to a minimum and is then dried continuously.

† By Dr. M. E. Holtquist and Dr. J. M. Smith, Jr. of the Calco Chemical Division, American Cyanamid Company, Pearl River, N. Y.

were supplied in crystalline form by placing them in capsules and administering them orally three times a week. The quantities given were as follows (mg per kilogram of body weight per day)

Thiamin hydrochloride	0.25	Pyridoxine hydrochloride	0.20
Riboflavin	0.12	Calcium pantothenate	0.50
Nicotinic acid	1.20	Choline chloride	10.00

In addition all animals received crystalline biotin 50  $\mu$ g per kilogram of body weight per week intramuscularly.

Hematologic studies (red blood cell count, hemoglobin, volume of packed red cells, red cell indices, reticulocyte count, total leukocyte count, differential leukocyte count and platelet count) were performed weekly on each animal throughout the entire experiment.

The cellular composition of the bone marrow was studied in each animal at the onset of the experiment and at the time of development of the deficiency, as well as before and after each therapeutic test. Specimens of bone marrow were obtained by aspiration of the sternal marrow with standard 16 gauge sternal puncture needles. A small amount of marrow fluid, usually less than 0.3 ml, was withdrawn into a clean dry syringe and then cover glass preparations were drawn and stained with Wright's stain. Differential cell counts were made on 500 to 1,500 cells. Because of the large amount of material the differential counts

FIG. 1.—Assay of purified and crude casein for extrinsic factor activity in a patient with pernicious anemia in relapse. The purified casein contained minimal extrinsic factor activity whereas 50 grams of the crude casein contained an amount presumably equivalent to 1 USP unit of liver extract, since no additional response followed the administration of this amount of liver extract.

will not be presented in detail in this publication. Photomicrographs of several types of cells as well as detailed differential counts were presented in the preliminary report.<sup>1</sup>

The total 24 hour urinary excretion of total hydroxyphenyl compounds (tyrosine, p-hydroxyphenyl lactic and p-hydroxyphenylpyruvic acids) expressed as the tyrosine equivalent and referred to as "tyrosyl" was determined by the Folin and Ciocalteu method<sup>24</sup> as modified by Medes.<sup>25</sup> The urine made weakly acid with acetic acid was shaken with fuller's earth to remove coloring matter and impurities capable of reacting with mercuric sulfate in subsequent procedures.<sup>26</sup> The intensity of the final color was measured in the Evelyn photoelectric colorimeter using filter 520 m $\mu$ . Commercial tyrosine, three times recrystallized,<sup>26</sup> served as a standard. Allantoin was determined in the urine by the method of Young and Conway,<sup>27</sup> using the Evelyn photoelectric colorimeter and filter 520 m $\mu$ . Recrystallized potassium allantoinate served as a standard. Urinary uric acid was determined by a modification<sup>28</sup> of the Kern and S. analysis method.<sup>21</sup>

## RESULTS

**General.** The animals deficient in pteroylglutamic acid presented an untidy appearance with thin, lusterless hair. Their growth was poor, although it was no more impaired than that of the low protein controls not given the antagonist.<sup>1</sup> On the 26 per cent casein diet growth was good but, by comparison with the controls,

curves of animals fed the basal diet plus 3 to 6 grams of yeast per kilogram of body weight,<sup>4</sup> there was a significant impairment of growth. At 120 days of age the four deficient animals given a 26 per cent casein diet (group B) weighed on the average 24.1 kilograms and at 180 days 46.1 kilograms. The weight of animals given yeast and no antagonist was 25 kilograms at 120 days of age and 67 kilograms at 180 days.

In addition, the deficient animals became listless, weak and ate poorly. Moderately severe diarrhea was present and the stools were somewhat orange-yellow in color, due presumably to the presence of antagonist. No oral lesions were observed. Spontaneous partial remissions of the pancytopenia occurred from time to time in the course of the experiment (figures 6 and 7). These remissions were usually associated with a slight reticulocytosis of 6 to 8 per cent. It is unlikely that the remissions were due to contamination of the diet since only one of two pigs kept in separate pens but eating out of a common trough might have a spontaneous response. A more plausible explanation would be that a favorable change in the synthesis of pteroylglutamic acid by the intestinal flora took place at times. Once the deficiency had become fully established, however, no further spontaneous remissions were observed.

It should be noted that the four pigs (10-53, 10-54, 10-56 and 10-64) described in the preliminary report<sup>1</sup> were depleted of pteroylglutamic acid for 80 to 120 days before the crude methyl folic acid antagonist was administered. These four pigs are included in group A. The remainder of the animals described here were given the antagonist from the beginning of the experiment.

**Red Blood Cells.** All four groups of animals developed severe macrocytic anemia (table 1), the only difference between the groups being in the rapidity of development and degree of macrocytosis. The administration of 26 per cent crude casein (group B) rather than 10 per cent crude casein (group A) delayed the onset of anemia by an average of 40 days. Anemia developed most rapidly in the animals receiving 10 per cent purified casein (group C), severe anemia being present in about 69 days as compared with the 160 days required in the animals fed 26 per cent crude casein (group B). As can be seen by inspection of the values for group D (table 1) the administration from the beginning of the experiment of 15 U.S.P. units of liver extract every 15 days did not prevent nor delay the appearance of anemia. The animals in group D were given a diet identical with that of group C.

The anemia in all four groups of animals was macrocytic. The mean corpuscular hemoglobin concentration was normal. However, the macrocytosis in group B was marked, whereas in group C it was only slight. The factors which seemed to determine the degree of macrocytosis are illustrated in figure 2. From this and from inspection of table 1 it can be seen that the degree of macrocytosis increased as time went on. An additional factor appeared to be the amount of protein in the diet since the group receiving 26 per cent casein (group B) developed a greater degree of macrocytosis in the same period of time than did the group receiving 10 per cent casein (group A). In the former group mean corpuscular volumes as great as 104  $\mu$  were observed.

The first change noted in the red cells was a marked anisocytosis. At the usual

number of macrocytes and microcytes were present. As the deficiency progressed the proportion of macrocytes increased. Poikilocytosis was not prominent at any time. An increase above the normal in the number of Howell-Jolly bodies, nucleated red blood cells and polychromatophilic cells generally took place. The anemia was associated with a slight reticulocytosis of 2 to 3 per cent (table 1).

FIG. 2.—Degree of macrocytosis in animals fed the crude, 26 per cent casein diet (Group B, solid line) compared with that in animals fed a crude 10 per cent casein diet (Group A, broken line). The data represent the means of values in all 4 pigs of Group B and 6 pigs studied for a corresponding length of time in Group A.

TABLE 2.—Summary of the Data on Leukocytes and Platelets

Group A, Crude casein, 10 per cent; Group B, Crude casein, 26 per cent; Group C, Purified casein, 10 per cent; Group D, Purified casein, 10 per cent plus liver extract, 15 units every 15 days.

PMN, polymorphonuclear cells including neutrophils, eosinophils and basophils.

MNC, mononuclear cells including lymphocytes and monocytes.

*Leukocytes* (table 2). Marked leukopenia accompanied the anemia, the absolute number of leukocytes being reduced to 50 to 58 per cent of their original values. The leukopenia resulted from a reduction in both polymorphonuclear and mononuclear cells but there was a proportionately greater reduction in polymorpho-

nuclear cells (52 per cent) than in mononuclear cells (44 per cent). All four groups of animals developed these changes to the same degree but the changes occurred much more rapidly on the purified than on the crude casein. Giant metamyelocytes and multinucleated neutrophils such as those seen in the blood smears of patients with pernicious anemia were not observed in the blood of the pigs.

*Platelets* (table 2). Slight thrombocytopenia developed. The values for individual pigs varied considerably but in general there was a slight reduction at the time of maximal anemia. No differences were noted between the four groups. Spontaneous rises occurred occasionally (figures 6 and 7).

*Sternal Marrow*. Differential cell counts on marrow obtained from the deficient animals revealed rather striking alterations from the normal. These are only summarized in table 3 since detailed differential counts were presented in the preliminary report.<sup>1</sup> No significant differences were noted between the four groups of animals. For this reason all the deficient animals are included in one group in the table.

TABLE 3.—*Summary of Bone Marrow Studies in Eight Pigs<sup>1</sup> Receiving a Complete Diet Low Only in Protein and in Twenty Pyruvylglutamic Acid Deficient Pigs*

Cell Type	Non Deficient Pigs	Deficient Pigs
Myeloblasts	0.9	1.7
Promyelocytes and Myelocytes	9.2	12.1
Metamyelocytes and PMN Neutrophils	49.3	22.2
Normoblasts	32.3	35.2
Megaloblasts	0.0	15.4
Leukocyte-Erythroid Ratio	2.1	1.0

Values represent means

There was a marked reduction in polymorphonuclear neutrophils and metamyelocytes and a slight increase in the proportion of myelocytes, promyelocytes and myeloblasts in the marrow of the deficient animals. The leukocyte-erythroid ratio was decreased. In addition, extremely immature nucleated red cells were present which differed from the basophilic normoblasts seen in the marrow of normal pigs and in those fed diets low in protein or deficient in iron. These cells were large, measuring 12 to 15 microns in diameter, and their nuclear chromatin was delicate and meshlike. In some cells the chromatin showed a tendency to clump, in others the chromatin appeared finely granular and more homogeneous. A delicate nuclear membrane separated the relatively large nucleus from the homogeneous basophilic cytoplasm. The more immature of these cells contained two or three distinct nucleoli. Later stages were present, including the orthochromatic stage. This entire series of cells constituted about 15 per cent (3 to 40) of all the bone marrow cells. Photomicrographs were included in the previous report.<sup>1</sup>

These cells resembled closely the megaloblasts seen in the marrow of patients with pernicious anemia, the only distinct difference being that the nuclear chromatin was not as fine and meshlike as that seen in megaloblasts in man. Whether

or not the cells described are pig megaloblasts is a matter for conjecture but for purposes of discussion in this paper these cells will be referred to as megaloblasts in order to distinguish them from the immature red cells (normoblasts) seen in other types of anemia in swine. It is noteworthy that these megaloblasts were present in the bone marrow in the same proportion in group D as in group A, B and C, in spite of the administration of liver extract from the beginning of the experiment.

*Tyrosyl, Allantoin and Uric Acid Excretion* The data on the urinary excretion of tyrosyl, allantoin and uric acid, both before and one month after pteroylglutamic acid therapy, are summarized in table 4. These represent the means of three consecutive daily determinations in each of 5 animals.

The term tyrosyl is used to refer collectively to the hydroxyphenyl compounds (tyrosine, p-hydroxyphenyllactic acid and p-hydroxyphenylpyruvic acid) as determined by the method of Folin and Ciocalteu.<sup>26</sup> No significant change was noted in the excretion of tyrosyl. Determinations were done daily on 2 animals for

TABLE 4—*Studies on the Urinary Excretion of Tyrosyl, Allantoin and Uric Acid in Pigs Before and After Pteroylglutamic Acid Therapy*

Determination	Number Pigs	Deficient	Treated
Tyrosyl mg	5	6.7 $\pm$ 1.38	8.0 $\pm$ 1.69
Allantoin mg	5	10.4 $\pm$ 1.37	7.8 $\pm$ 0.91

Allantoin + Uric Acid mg	5	16.5 $\pm$ 1.68	13.3 $\pm$ 1.71

Results are expressed in mg./kilo body weight/24 hours

thirty days following therapy. No consistent increase or decrease was noted either within the first day or two, or later. The amount excreted per day by a single animal varied from day to day as much as 575 mg.

The 24 hour urinary excretion of allantoin and uric acid was not significantly different before therapy as compared with the excretion one month later. However, immediately following therapy, in association with the reticulocytosis, there was a marked increase in the excretion of allantoin as shown in figure 3. A similar increase in uric acid excretion did not occur.

*Pathologic Studies\** Autopsy material including sternal, rib and femoral bone marrow, liver, spleen, stomach, kidney, lung, skeletal muscle and cardiac muscle, was obtained from 7 untreated animals in which a deficiency of pteroylglutamic acid had been produced. The bone marrows showed a striking cellular hyperplasia. Megakaryocytes were present in approximately normal numbers except in the marrow of pig 10-88. This animal had a marked thrombocytopenia (72,000 per cu mm) just prior to death, and the number of megakaryocytes was reduced.

Microscopic examination of the liver, spleen, kidneys, lungs and cardiac muscle failed to reveal any significant abnormalities although small areas of interstitial

\* We are indebted to Dr. F. D. Gunn, Professor of Pathology, University of Utah, for these studies.

hemorrhage were seen in sections of the lungs of two animals. An increase in hemosiderin was not observed in any of the organs studied. Areas of atrophy, hyalinization and segmental necrosis were present in the sections of skeletal muscle. Similar changes have been observed in the muscles of animals fed a diet low in protein.

*Response to Various Therapeutic Agents* The increases in reticulocytes and volume of packed red cells following therapy with pteroylglutamic acid compounds (23 animals) are summarized in table 5. Representative examples are illustrated in detail in figures 4, 5, 6, 7 and 8. In every instance except two, a reticulocytosis of

FIG. 3.—Urinary excretion of uric acid and allantoin (fig 10-75 Group B) following a single intramuscular injection of 10 mg of pteroylglutamic acid. Note the marked increase in the excretion of allantoin during the period of reticulocytosis. The excretion of uric acid remained relatively constant.

11 per cent or greater followed therapy with a pteroylglutamate. In half of the animals treated there was a reticulocytosis of 21 to 42 per cent. The reticulocyte curve rose sharply with a peak on either the third or fourth day following therapy, as illustrated in figure 4, in all but two instances. In these the peak was reached on the second and fifth days, respectively. Simultaneously with or just following the reticulocytosis there occurred a rapid rise in the volume of packed red cells and a return to normal or near normal values within two to three weeks. Frequently the increase was as great as 10 to 15 ml/100 ml in the first week following therapy (figure 4). In all instances except two the increase was greater than 10 ml/100 ml and in one-half of the animals the rise was greater than 15 ml/100 ml. The mean corpuscular volume returned to normal more slowly and frequently macrocytosis persisted in the absence of anemia.

An initial leukocyte increase, generally greater than 5000 per cu mm, invariably followed this type of therapy (table 8). After several weeks the leukocytes then decreased somewhat but in 20 of the 23 animals so treated the values for total leukocytes were sustained within the normal range. A thrombocytosis also oc-

curred in almost every instance but due to the great variability in the number of platelets the results are difficult to interpret

In the bone marrow pteroylglutamic acid therapy was associated with a reversion to normal. There was a decrease in the megaloblast-like cells, an increase in the myeloid-erythroid ratio and a shift to the right in the myeloid series. Frequently large masses of platelets, covering several low-power fields, were present in the bone marrow preparations.

PTGA pteroyltriglutamic acid

PHGA pteroylheptaglutamic acid

V.P.R.C. volume of packed red cells

Pteroyldiglutamic acid (figure 4), pteroyltriglutamic acid (figure 8) and pteroylheptaglutamic acid were as effective as pteroylglutamic acid (table 5) in restoring the blood and bone marrow to normal. The one animal (10-97) treated with the diglutamate, one (10-98) of the four animals treated with the triglutamate and both animals (10-85, 10-96) treated with the heptaglutamate were fed the purified casein diet and so presumably had received little extrinsic factor.

The effects of therapy with various commercial liver extracts and with vitamin

FIG 4.—Fig 10-97 (Group C purified casein, 10 per cent) Note the marked reticulocytosis and increase in volume of packed red cells (Ht), leukocytes (WBC) and polymorphonuclear cells (PMN) following the intramuscular administration of 50 mg of pteroyldiglutamic acid

MCV refers to mean corpuscular volume in  $\mu$ , Ht refers to volume of packed red cells, ml/100 ml retic refers to reticulocytes, per cent WBC refers to total leukocyte count thousands per c mm PMN refers to polymorphonuclear cells thousands per c mm, Plat refers to platelets times 100 000 per c mm

FIG 5.—Fig 10-72 (Group B, crude casein, 26 per cent) Note the reticulocytosis and gradual increase in the volume of packed red cells (Ht) following the intramuscular administration of 2 ml (No 1039 30 USP units) of purified liver extract This represents the greatest response to liver extract observed Compare with figures 7 and 8 After becoming anemic again this animal failed to respond to a second injection of liver extract (No 1039 30 USP units) although it responded promptly to 20 mg of pteroyldiglutamic acid intramuscularly It is noteworthy that this animal was receiving 26 per cent crude casein and consequently had available liberal amounts of extrinsic factor For symbols see figure 4

B<sub>12</sub> are presented in table 6. Representative examples are illustrated in figures 5, 6, 7, 8. A significant reticulocytosis of more than 10 per cent occurred in 33 per cent

FIG. 6—Pig 10-92 (Group D, purified casein 10 per cent plus 15 U S P units of purified liver extract (No. 1039, 15  $\mu$ /ml) every 15 days). This animal developed anemia, leukopenia, neutropenia, and thrombocytopenia in spite of the administration of 15 units of purified liver extract every 15 days from the beginning of the experiment. The intramuscular administration of 10 ml (150 units) of the same liver extract in a single injection was followed by a reticulocytosis but there was no increase in volume of packed red cells (Ht.). Twenty mg of pteroylglutamic acid (intramuscularly) produced a prompt response in reticulocytes and volume of packed red cells. For symbols see figure 4.

FIG. 7—Pig 10-95 (Group C, purified casein 10 per cent). Following the intramuscular administration of 2 ml of purified liver extract (No. 1124, 40 units) there was a slight reticulocytosis but no increase in the volume of packed red cells (Ht.). This animal failed to respond to liver extract in spite of the fact that he was given purified casein (extrinsic factor poor). A rapid response took place following the administration of 20 mg of pteroylglutamic acid intramuscularly. For symbols see figure 4.

(5 out of 15) of the trials whereas a similar response occurred in 91 per cent (21 out of 23) of the therapeutic trials with the pteroylglutamates. The reticulocyte curve in general rose gradually, was flat in shape and the peak, if present, was delayed

(figures 5, 6, 7) as compared with the peaks following pteroylglutamic acid therapy (figures 4, 5). The reticulocyte response to liver extracts was no greater in the

FIG. 8—Fig 10-78 (Group A, crude casein 10 per cent) Note the failure to respond to tyrosine liver extract (No. 1124, 20 units followed by 60 units and No. 1067, 40 units) and the subsequent response to a single intramuscular injection of 20 mg of pteroylglutamic acid. For symbols see figure 4.

5-10	12	2
10-15	7	0

curve was irregular and was not accompanied by a rise in volume of packed red cells

A significant increase in the volume of packed red cells following liver therapy was observed in only 5 pigs (10-54, 10-56, 10-72, 10-77, 10-80) and in these the rise was 8, 12, 14, 13 and 8 ml /100 ml respectively By comparison, pteroyl glutamic acid therapy was followed by a rise in the volume of packed red cells greater than 10 ml /100 ml in 91 per cent of the trials The rise was prompt as well as marked In general, the mean corpuscular volume was little affected by liver extract therapy (figures 6, 7, 8)

An initial increase in leukocytes following liver therapy occurred in 12 out of 15 trials but it was not as marked as the rise following pteroylglutamic acid therapy (table 8) In 10 instances the leukocyte level was sustained within the normal

range Thrombocyte increases occurred irregularly but in general the increases were not sustained

The changes in the bone marrow which followed liver therapy were of the same type and degree as the changes noted in the peripheral blood. In most instances, as the number of leukocytes rose following the injection of liver, there was an increase in metamyelocytes and neutrophils and an increase toward normal in the leukocyte-erythroid ratio. In the bone marrow of those animals in which the anemia responded partially to liver therapy there was a reduction in the relative numbers of megaloblast-like cells but in no instance did they disappear entirely. If no response to liver was observed, no changes were noted in the bone marrow.

Crystalline vitamin B<sub>12</sub> was administered to one pig (table 6). The reticulocytes rose from 1 to 6 per cent and the volume of packed red cells increased from 20 to 31 in 29 days.

The results of therapy with various other substances are presented in table 7. Uracil, adenine and tyrosine were inactive in the doses given. Xanthopterin in a single injection of 20 mg (1 mg/kilogram of body weight) produced, in a single animal, a slight reticulocytosis of 9 per cent and a small unsustained rise in volume of packed red cells. This was then followed by 25 mg (1.9 mg/kilogram) of xanthopterin daily by mouth for five days without a further response. A response to thymine with a reticulocytosis of 21 per cent was observed in one animal (10-81). Although the volume of packed red cells, leukocytes and platelets increased, the increase was not maintained and a second course of thymine was ineffective. In two other pigs (10-76, 10-77) no response followed the administration of thymine.

#### DISCUSSION

Macrocytic anemia, leukopenia due to a proportionately greater reduction in polymorphonuclear than in mononuclear cells, slight thrombocytopenia, and a bone marrow picture showing erythroid hyperplasia and immature red cells resembling the megaloblasts of pernicious anemia, developed in swine fed low or high levels of crude or purified casein and given sulfasuxidine and a pteroylglutamic acid antagonist. A clear cut and sharp hemopoietic response was observed in such animals whenever pteroylglutamic acid was given. The administration of liver extract, however, was associated with only a slight effect. Thus, in 10 out of 15 trials, no or only slight activity was observed. In 5 trials a significant reticulocytosis occurred but the reticulocyte peak was delayed and the curve was flat as compared with that produced by pteroylglutamic acid. Although an increase in volume of packed red cells followed liver extract therapy in 5 pigs, this increase was delayed, submaximal and unsustained.

These blood and bone marrow changes developed in the experimental animals not only when crude casein containing extrinsic factor was fed, but even in pigs injected every 15 days with liver extract containing 15 units of anti-pernicious anemia principle. Thus it seems clear that a hematologic syndrome with morphologic characteristics similar to those of pernicious anemia can be produced experimentally in the pig in the presence of the anti-pernicious anemia liver factor. This condition would appear to be similar to the pteroylglutamic acid-responsive, liver-

refractory megaloblastic anemias described in human subjects, namely, tropical macrocytic anemia,<sup>44</sup> <sup>45</sup> <sup>46</sup> macrocytic anemia of pregnancy,<sup>47</sup> achrestic anemia,<sup>48</sup> and refractory megaloblastic anemia<sup>49</sup>

It is not likely that the response to liver extract, such as it was, can be attributed to the pteroylglutamic acid content of the extracts. More than 50  $\mu\text{g}$  of pteroylglutamic acid has been found to be required by the pig in order to elicit a significant response (table 6). The extracts used were found by assay with *Lactobacillus casei* in our laboratory as well as by others<sup>20</sup> to contain only about 1 to 5  $\mu\text{g}$  of the vitamin per ml, and the greatest response to liver extract (pig 10-72) occurred following the injection of only 2 ml. Furthermore, there was no correlation between the number of ml of extract given and the degree of response. Again, extracts containing no anti-pernicious anemia activity (nos. 1063 and 1066) but possessing the same quantities of pteroylglutamic acid were ineffective. The less highly purified extract (no. 1067, 4 units/ml) containing about 5  $\mu\text{g}$  of pteroylglutamic acid per ml was no more effective in the pig than the more highly refined extract (no. 1124, 20 units/ml) which contained only about 1  $\mu\text{g}$  per ml.

Since the response following the administration of crystalline vitamin  $\text{B}_{12}$ \* was of the same type as that following purified liver extract, it is reasonable to assume that the effectiveness of the liver extracts was due to their vitamin  $\text{B}_{12}$  content (or to a chemically related substance) rather than to a third factor and that in those pigs responding to liver extract there existed a partial deficiency of the liver factor in addition to the pteroylglutamic acid deficiency. Consistent with this is the observation that pig 10-72 (fig. 5) failed to respond to a second injection of liver extract after becoming anemic a second time. Presumably the deficiency had been satisfied by the injection of liver extract and a second response was therefore not obtainable.

Animals receiving crude casein containing considerable extrinsic factor activity responded as well to liver extract as did those receiving purified casein. It must be concluded, therefore, that a partial deficiency of liver principle developed in spite of the availability of extrinsic factor. On the other hand, pigs fed a diet similar in all respects to the low protein diet used in these experiments, with the exception that a pteroylglutamic acid antagonist was not included, did not respond at all to liver extract.<sup>51</sup> This suggests that in pteroylglutamic acid deficiency the requirement for a factor in liver extract (vitamin  $\text{B}_{12}$ ) is increased. One may speculate whether pteroylglutamic acid plays a role in the release, absorption or synthesis of vitamin  $\text{B}_{12}$  in the intestinal tract.

The hypothesis has been presented<sup>52</sup> that pteroylglutamic acid functions in some way in the synthesis of thymine and that  $\text{B}_{12}$  serves as a coenzyme which is concerned with the conversion of thymine to thymidine. According to this hypothesis, the curative effects of pteroylglutamic acid in pernicious anemia depend upon increased thymine synthesis, which, by mass action, leads to the formation of thymidine. The effectiveness of large amounts of thymine in pernicious anemia is explained on a similar mass action hypothesis. If this view is correct, then pigs

\* This finding has been confirmed in five additional pigs.

deficient in pteroylglutamic acid should respond to large doses of thymine. Such was not the case.

The pteroylglutamic acid deficient swine, receiving either crude or purified casein, responded rapidly and maximally to each of the three pteroylglutamic acid conjugates tested. This indicates that in these animals there was adequate utilization of the conjugates. If the animals were actually in a state of liver factor depletion, as suggested by assays of the livers of similar animals,<sup>11</sup> then it is difficult to accept the hypothesis that the liver factor is necessary for the proper utilization of the naturally occurring conjugates.<sup>52</sup> However, it must be admitted that it is much easier to find flaws in current hypotheses concerning the role of pteroylglutamic acid and the anti-pernicious anemia factor in metabolism than it is to offer an explanation which is wholly satisfactory.

Swendseid, Wandruff and Bethell<sup>54</sup> have found that the urinary excretion of total phenols and hydroxyphenyl acids is increased in patients with pernicious anemia in relapse and that within twenty-four hours following therapy with liver extract there is a marked reduction in the phenolic fraction containing the hydroxyphenolic acids. It has also been claimed that liver suspensions from pteroylglutamic acid deficient rats are better able to oxidize tyrosine after the addition of pteroylglutamic acid than in the absence of this substance<sup>55</sup> and that either pteroylglutamic acid<sup>56</sup> or anti-pernicious anemia liver extracts<sup>57</sup> are capable of reducing the increased keto acid and tyrosyl excretion in scorbutic guinea pigs. The results of the tyrosyl excretion studies presented here fail to indicate the presence of a defect in tyrosine metabolism in pigs.

The markedly increased excretion of allantoin in the urine during the period of reticulocytosis following therapy with pteroylglutamic acid is similar to the increase in uric acid excretion which occurs in patients with pernicious anemia following therapy with liver.<sup>58</sup> However, since a similar increased excretion takes place during the regenerative phase following hemorrhage,<sup>59</sup> it is likely that this merely represents increased hemopoietic activity and a rapid turnover of nucleic acids in the bone marrow.

#### SUMMARY

1 A deficiency of pteroylglutamic acid has been produced in 32 swine fed a purified diet containing casein and supplemented with seven B vitamins, sulfasuxidine and a folic acid antagonist. The casein was fed at two levels, 10 and 26 per cent. Two types of casein were used: a crude preparation possessing significant extrinsic factor activity and a purified casein with little activity.

2 The hematologic manifestations observed were (a) severe macrocytic anemia, (b) leukopenia, due to a proportionately greater reduction in polymorphonuclear than in mononuclear cells, (3) slight thrombocytopenia, and (4) hyperplastic bone marrow with an increase in immature nucleated red cells which resemble the megaloblasts seen in the bone marrow of patients with pernicious anemia.

3 The feeding of a 26 per cent rather than a 10 per cent crude casein diet did not prevent but did delay the onset of the blood changes. Anemia developed most rapidly in the animals receiving 10 per cent purified casein.

4 The group receiving 26 per cent casein developed a greater degree of macrocytosis in the same period of time than did the group receiving 10 per cent casein. In all groups the degree of macrocytosis increased as the duration of the anemia increased.

5 The hematologic manifestations were not delayed nor was their development prevented by the intramuscular administration of 15 U S P units of liver extract every 15 days.

6 The blood and bone marrow returned rapidly to normal following the administration of pteroylglutamic acid, pteroyldiglutamic acid, pteroyltriglutamic acid and pteroylheptaglutamic acid. Thymine and xanthopterin had little or no activity. Tyrosine, adenine and uracil were inactive.

7 Purified liver extracts and crystalline vitamin B<sub>12</sub> were found to possess some hemopoietic activity in several animals but the activity was considerably less than that of the pteroylglutamic acid compounds.

8 The urinary excretion of tyrosyl (hydroxyphenyl compounds) was not abnormal in the pteroylglutamic acid deficient pigs and was not altered by either pteroylglutamic acid or liver extract therapy.

9 The urinary excretion of allantoin and uric acid did not differ significantly from the normal. Immediately following therapy with pteroylglutamic acid, however, in association with the reticulocytosis and lasting for the same period, there was a marked increase in the excretion of allantoin.

10 The results suggest that both pteroylglutamic acid and a factor in liver extract similar to or identical with vitamin B<sub>12</sub> are required for normal hemopoiesis in the pig.

#### ACKNOWLEDGEMENTS

The crude methylfolic acid antagonist xanthopterin and the pteroylglutamic acid compounds, with the exception of pteroylheptaglutamic acid, were kindly furnished by the Lederle Laboratories, Pearl River, New York, through the courtesy of Dr. T. H. Jukes and Dr. S. M. Hardy.

Sulfasuxidine was generously furnished by Sharp & Dohme, Inc., Philadelphia, Pa., through the courtesy of Dr. W. A. Feiler.

Pteroylheptaglutamic acid and Natola were supplied by Parke, Davis & Company, Detroit, Mich., through the courtesy of Dr. A. E. Sharp and Dr. J. J. Pflieger.

Biotin was obtained from Hoffmann-La Roche, Inc., Nutley, N. J., through the courtesy of Dr. E. L. Severinghaus.

The vitamins, with the exception of pteroylglutamic acid and biotin and including vitamin B<sub>12</sub>, were kindly furnished by Merck and Company, Inc., Rahway, N. J., through the courtesy of Dr. A. Gibson and the late Dr. D. F. Robertson.

Experimental liver extracts (No. 1124, 1063, 1066 and 1067) were generously furnished by Armour and Company, Chicago, Illinois, through the courtesy of Dr. E. E. Hays.

We are indebted to Mrs. Darlene Kehl, Mr. George Trappett and Mr. Otis Hadley for technical assistance.

# THE USE OF REPLACEMENT TRANSFUSION IN DISEASES OTHER THAN HEMOLYTIC DISEASE OF THE NEWBORN

By M. BESSIS, M.D.

## INTRODUCTION AND HISTORY

**R**EPLACEMENT transfusion is an operation which combines blood letting and transfusion at the same time and in the same patient. The idea of using this technic is very old, it is interesting to recall that the first physicians who tried transfusions in the seventeenth century began by doing replacement transfusions. Eutyphronus remarked, "It is foolish to transfuse a patient without previous blood letting, because this would not reduce the strain on the body."

This operation, although it had a few successes, caused quite a few deaths. This is easily understood since the transfusions were usually done with animal blood. After the report of Claude Perrault to the Academy of Science in Paris in 1664, this body declared the transfusion a dangerous method. In 1675, Parliament passed a law prohibiting its use.

Since the discovery of blood groups by Landsteiner, the use of transfusion has increased greatly, but replacement transfusion was almost completely abandoned. At most, it was used in a few cases of carbon monoxide poisoning, mushroom poisoning, and intensive burns. Even in those cases, only one blood letting and a transfusion of 500 to 1000 cc. was performed. The purpose of this article is to discuss not replacement transfusion as it was used then, but the replacement of the total blood volume of a patient by the blood of many donors and the repetition of that technic many times in the same patient.

The progressive realization of a complete blood replacement in man was achieved in 1946. We had thought for some time that such an operation would be of great value if it was well tolerated by the patient. In 1939-1940 we studied with our director, A. Tzanck, and our associate, M. Burstein, a technic for rapid replacement transfusion in the dog. We showed that in that animal the total blood volume could be replaced by a mixture of fresh blood of other dogs without any serious reaction. We achieved thus not a simple blood letting followed by transfusion, but a true "washing out" of the organism. At the same time, we attempted similar results in man, but did not succeed completely. After the war, in 1945-1946, studies on the Rh factor and hemolytic disease of the newborn gave a new impetus to this problem.

It is known that in hemolytic disease of the newborn the infant has in his body both Rh positive blood cells and anti-Rh serum. A few persons thought that the most rational treatment would be replacement transfusion of the newborn. That operation was proposed and carried out by Wallerstein, Wiener, Bessis, and others. A further advance was realized with the method of Diamond who uses a plastic

From the Research Laboratory of the National Center of Blood Transfusion, Paris, France

catheter which is pushed up to the main vessels and which enables total replacements\* to be done under ideal conditions

In spite of the successes of replacement transfusion in the newborn, the same operation had not, to our knowledge, been used in adults until 1947. The recent progress in immunology following discovery of the Rh factor and similar blood groups and of the conditions under which a person can have irregular agglutinins, led us to attempt such an operation. Although there was a possibility that repeated transfusions might cause some reactions of incompatibility due to rare or still unknown antigens, the fact that the majority of those accidents are due to Rh or similar factors which can be prevented by careful selection of donors justified our attempt.

There was also the possibility of reactions due to intolerance on the part of the recipient or transmitted by the injected blood, accidents whose possible frequency is multiplied by the number of donors. This is the reason why our first experiences were performed on a very limited scale and only on patients suffering from incurable disease and in a moribund state. Little by little, however, we have attempted more complete transfusions. Led by an hypothesis which we will discuss later, we tried total replacement transfusion in a child suffering from acute leukemia. This operation was successful and proved thereby both the innocuousness of the replacement transfusion and its action in leukemia.

Our experience, which is based on over 190 replacement transfusions† in children and adults, has confirmed the first proof, because we have had no serious accident. Moreover, in all these cases the general condition of the patient was clearly and rapidly improved. We shall discuss later the precautions which must be observed in the choice of blood to be injected, and our results. We do not wish to say that the fear which we had before trying the procedure is unjustifiable, because an accident is always possible.

The results which we report in this article are not of equal value. Many patients, treated in the early period of trial, received only one replacement transfusion. The operation was not repeated either because we did not know then that one replacement transfusion was insufficient or because we had difficulty in getting blood of the proper group or because of absence of suitable veins. As an example, we can take the first case of acute anuric nephritis in which we did only one replacement transfusion and obtained no results. It was only with experience that the necessity for repeating the replacement transfusion at intervals varying with the condition of the patient became evident and that we obtained consistently good results.

\* By total replacement we mean replacement of 85 to 95 per cent of the blood volume, and this is done by replacement transfusion of two to three times the patient's blood volume. (This is explained more fully in the section on "Technic.")

† These include, cases of acute anuric nephritis, acute leukemia, chronic leukemia, lipid nephrosis, generalized carcinoma, severe icterus, myeloma, lymphosarcoma, acute polyarthritis, and acute hypertensive nephritis.

## I TECHNIC OF REPLACEMENT TRANSFUSION IN THE CHILD AND IN THE ADULT

We will give here the principle of the method, and those interested in technical details may refer to the work of S. Buhot. The drawing and injection of the blood are done at the same time so that the total volume is unchanged. In these conditions the percentage of the transfused blood in the organism as compared to the quantity injected is as follows (after Wiener and Wexler)

<i>Quantity of blood injected</i>	<i>Percentage of blood transfused in the patient's organism</i>
$\frac{1}{2}$ volume of patient's blood	39.4
1 volume of patient's blood	63.2
$1\frac{1}{2}$ volumes of patient's blood	77.7
2 volumes of patient's blood	86.5
$2\frac{1}{2}$ volumes of patient's blood	91.8
3 volumes of patient's blood	95.0

The first problem is to find the necessary quantity of blood for the replacement transfusion. For an adult who has an average blood volume of 5 liters, we need 15 liters, usually obtained from 30 donors, and these must be of the same ABO and Rh groups. If we cannot get sufficient blood of the proper A or B group, we use O group blood after neutralizing the anti-A and anti-B agglutinins with Wittebsky's AB substances.

We use fresh blood collected in bottles containing citrate solution. Our experience has shown that such transfusions are well tolerated by the patient and give no serious reactions if we give calcium intravenously to prevent tetany caused by the fixation of the blood calcium to the sodium citrate. Lately we have modified our technic and have used heparin, 2 mg per kilo of body weight, since the clotting time of the patient during the operation is so lowered as to render the drawing of blood very difficult.

We draw the blood either from a vein of the elbow on the side opposite to the injection or from the femoral vein. We use vacuum bottles to obtain a rapid flow of blood. However, the easiest method is to use a plastic catheter as suggested by Diamond for replacement transfusion in the newborn, and to introduce it in a superficial vein either after cutdown or through a large bore needle, pushing the tip up to one of the larger veins. It is then easy to draw the desired amount of blood and to inject by the same route. The rapid flow of blood in the large veins prevents us from withdrawing the blood which we have just injected. The catheter also spares the patient the inconvenience of the pressure cuff which is very painful after a time.

Lately we have simplified the operation by the use of the electrical pump of Dausser and Moulinier which is essentially a plastic pump electrically driven and with a reversible action. One end is connected to the plastic catheter and the other to the donor's blood flask and to the used blood receptacle. The pump draws the blood from the patient at any desired speed, e.g., 300 cc. in 5 minutes. The flow is then reversed and the pump is used to transfuse the patient with donor's blood. This operation is repeated until the desired number of liters has been given. Only two persons are needed for the whole procedure, which includes the drawing of the

FIG. 1.—EXSANGUINO TRANSFUSION PERFORMED IN A HUMAN ADULT

The injection is done on one side the bleeding on the other. The same route can be used for both injection and bleeding by using the special pump of Dausset and Moulinier.

FIG. 2.—EXSANGUINO-TRANSFUSION PERFORMED ON A CHILD

Bleeding is done with the help of a catheter (Diamond) so as to reach a large blood vessel. Same remark as for figure 1.

blood from the donors. We have thus been able to draw from the patient and to transfuse 16 liters of blood in 3 hours. The operation lasts from one hour in the child to two to four hours in the adult.

The reactions we encountered are of little gravity—chills and urticaria—but they are more frequent than with the usual transfusions (30% of the cases). This may be due to the fact that our material was not checked for pyrogenic substances. Sometimes we have seen a temperature rise which lasted one to two days.

## II. TREATMENT OF CERTAIN INTOXICATIONS AND ANURIC NEPHRITIS BY REPEATED REPLACEMENT TRANSFUSIONS

The indication for replacement transfusion is evident in the course of an intoxication when the toxic product is in the blood, for example, in hemolytic disease of the newborn where the antibodies and the coated red cells are circulating in the serum. Other examples are cases of severe intoxication due to benzol, potassium chlorate, etc. But replacement transfusion is also indicated when the toxic product is produced by the organism itself and is found in the blood. By this we mean hemoglobinemia and other products of hemolysis whatever may be the cause—septicemia, hemolytic poisons, crush syndrome, and the transfusion reactions due to incorrect grouping or typing. In all these conditions replacement transfusion combats the anemia and, what is more important, replaces the pathological plasma with normal plasma, thus preventing or diminishing the secondary renal reactions.

However, we think that the most important indication for replacement transfusion is in anuric nephritis.\* In these cases the kidneys, although they have been subjected to a great insult, are capable of regaining their previous morphologic and physiologic status. This is supported by the postmortem findings of anatomical lesions in various stages of repair. Thus we have the impression that if those patients could have survived a few days the disease would have tended to end favorably. In these cases, replacement transfusion, by withdrawing with the patient's blood the toxic products contained in it and replacing this blood with normal blood, plays the role of eliminatory organ and allows the survival during the time necessary for the kidneys to regain their normal function. We have observed that replacement transfusions of moderate size (5 liters), repeated every second or third day† withdraw sufficient urea (25 Gm. from a patient whose urea blood level is 500 mg. per cent) and other toxic products to enable survival of the patient until the return to normal of the kidney function. The records of the patients treated in this manner have already been published. We will mention here one of the observations.

\* These replacement transfusions have evidently no resemblance to the operation described by Carrel and Joltrain under the name of washing the blood which consists of withdrawing small quantities of the patient's blood, washing the red cells in normal saline and reinjecting the washed blood into the patient.

† Some persons have questioned whether the withdrawal of blood has any effect on the N urea level. We have noted, as can be seen by our charts, that the first replacement transfusion does not change the urea level. This is proof that the urea of the tissues has diffused in the normal blood injected. After several replacement transfusions, however, the abnormal urea of the tissues is slowly lowered and the blood urea level tends to return to normal.

## CASE REPORT\*

A patient 26 years old entered the hospital February 18 1948 following an intentional abortion with the clinical findings of a septicemia due to *B. perfringens* which was confirmed by blood culture February 19. She was treated by massive doses of penicillin. On February 20 the RBC was 1 620 000 per cc. and her serum was strongly icteric, as was her skin. She was in marked oliguria. A replacement transfusion of 8 liters was given and considerably improved her general condition. The icterus disappeared in twelve hours. The RBC the next day was 4 070 000. The serum was of a normal color, the toxic products of acute hemolysis having been eliminated. There appeared slight purpura and the patient was in severe oliguria with a urea level of 250 mg per cent. This oliguria persisted for twenty two days. During that time we performed five replacement transfusions of 4 to 6 liters each, withdrawing each time 15 to 25 Gm of urea and other toxic products. These operations were well supported by the patient, and normal diuresis was gradually regained. The urea level fell slowly until it was normal on April 1.

FIG. 3.—Evolution of blood urea (dots 1 = 1 Gm), volume of urines (thick line 1 = 1 liter) urea eliminated per day (fine line 1 = 10 Gm) the principle observation of anuric nephritis treated by exsanguino transfusion. The black columns indicate the urea amount drawn out by successive exsanguinations (1 = 10 Gm) (observation made by P. V. Ravor and M. Millicez and co-workers).

This observation shows that (1) Replacement transfusion is able to transform a person suffering from uremia from a preagonal to a normal condition in a few hours. (2) This operation removes the greater part of the toxic products of acute hemolysis and, if done before the anuria sets in, possibly diminishes the secondary renal complications. (3) Repeated massive replacement transfusions can, for a short time, act like the kidneys, thus allowing survival until kidney function is regained. (4) The urea concentration in the urine remains very low in spite of the

\* Pasteur Vallery Rador, Millicez and colleagues.

FIG. 4.—Evolution of Acute Nephritis Treated Successfully by Exchanging Transfusion Same symbols as figure 3 (Patient of A. Tzanck and J. Dausset)

FIG. 5.—Same remark as figure 4

return to normal of the urea level of the blood, and this fact, added to the numerous observations of patients cured by dialysis, confirms the opinion that the kidney lesions regress very slowly. On the average it takes three months for complete recuperation. Dr. Dausset has treated 6 other cases of anuric nephritis of which three had been treated previously or alternatively by intraperitoneal dialysis and were in a moribund state. The 6 cases survived. The data are given in figures 4-5.

A comparative chart of the effects of the replacement transfusion as compared to those of intraperitoneal dialysis follows:

Replacement Transfusion	Intraperitoneal Dialysis
1. Removes all the toxic products including the nondialyzable ones such as hemoglobin, myoglobin, stromatol	1. Removes only the dialyzable toxic products
2. Does not modify the normal equilibrium of the tissue fluids	2. Unless special precautions are taken, normal equilibrium is destroyed either by adding or taking away too much electrolytes or adding too much water which may lead to cerebral edema
3. Does not cause any severe reactions	3. Usually causes peritonitis either of the plastic type by the formation of adhesions or, in certain cases, the infectious type
4. Can be used as often as needed	4. Possibility of peritonitis prevents its continuous use for more than a few days and frequently prevents its reuse
5. Is very efficient: removes a larger quantity of toxic products which can be calculated beforehand	5. Removes a lesser quantity which cannot be calculated beforehand
6. Painless and rapid	6. Inconvenient and slow

### III REMISSIONS IN ACUTE LEUKEMIA TREATED BY REPLACEMENT TRANSFUSIONS

The principle behind the use of replacement transfusion in leukemia is based on the hypothesis that there is an antileukemic substance in normal blood. This hypothesis is based on the good results which have been occasionally noted after ordinary transfusions. Clinical and hematologic remissions in leukemia after transfusion have always been rare, but they can not be denied, as was reported by Dreyfus. In addition to those complete remissions, cases of clinical and peripheral blood improvement have been frequently reported after transfusion. However, no one paid much attention to these remissions, and Wintrobe, in his *Clinical Hematology* (1947 edition), says in brief that transfusions in leukemia can be used against the anoxemia and the bleeding, and that in one case he had noticed a remission of a few months' duration, which however could not be repeated. He goes on to say that in view of the expense and trouble and temporary effect, there are few indications for transfusion in acute leukemia.

We believe that we have proven in the 38 cases which we have treated that, contrary to what has been reported after single transfusions, total or partial remissions

(2) In 30 cases, we witnessed in succeeding days a clinical remission consisting in the disappearance of adenopathy, hepatosplenomegaly, temperature, etc. In 15, these clinical remissions were accompanied by the return to normal of the peripheral blood and an amelioration of the marrow, and in 6 of these there was complete clinical, peripheral blood, and marrow remission (3) The remission lasted in general three weeks to three and one-half months. However, of the patients with complete remission are still alive after eleven months, or in complete remission, the other in clinical remission. The other four complete remissions lasted one to three and one half months. When a patient relapsed, the clinical

FIG. 9.—Sternal puncture of same patient as in figure 8 but after a series of frequently repeated exsanguino transfusions (Observation made by Fagart and Angibeaux. *Rev. Hemat.* 4, 1948)

remission was less marked, although due to diverse reasons transfusion was not fully used in all the patients.

These results have been duplicated in a few other centers in France. Though not by no means perfect, this technic brings some hope to the leukemics and indicates a new approach to the problem of acute leukemia.

#### IV POSSIBLE INDICATIONS OF REPLACEMENT TRANSFUSIONS IN MEDICAL RESEARCH

To bring to the attention of other persons interested in research and the diseases the possibilities of this technic, we shall examine it rapidly for its usefulness in (a) withdrawing toxic products from the organism, (b) injecting in physiologic quantities the important substances which a normal person has in his

FIG. 7—Bone marrow puncture done on same patient as in figure 6 but after three exsanguino transfusions

FIG. 8—Sternal puncture performed on a patient with acute leukemia

(2) In 30 cases, we witnessed in succeeding days a clinical remission consisting of the disappearance of adenopathy, hepatosplenomegaly, temperature, pain, bleeding. In 15, these clinical remissions were accompanied by the return to normal of the peripheral blood and an amelioration of the marrow, and in 6 of these there was complete clinical, peripheral blood, and marrow remission (3) The remission lasted in general three weeks to three and one-half months. However, 2 of our patients with complete remission are still alive after eleven months, one in complete remission, the other in clinical remission. The other four complete remissions lasted one to three and one-half months. When a patient relapsed, the effect of re-

placement transfusion was less marked, although due to diverse reasons transfusion was not fully used in all the patients.

These results have been duplicated in a few other centers in France. Though it is by no means perfect, this technic brings some hope to the leukemics and indicates a new approach to the problem of acute leukemia.

#### IV POSSIBLE INDICATIONS OF REPLACEMENT TRANSFUSIONS IN MEDICAL RESEARCH

To bring to the attention of other persons interested in research and blood diseases the possibilities of this technic, we shall examine it rapidly for its usefulness in (a) withdrawing toxic products from the organism, (b) injecting in physiologic quantities the important substances which a normal person has in his blood.

and which are lacking in sick persons, (c) studying the evolution of a disease in a subject whose blood has returned to normal, (d) realizing better a condition of parabiosis between a patient and a healthy donor

(a) *The replacement transfusions enable the withdrawal of toxic substances* This fact is evident when the substance is known and can be calculated in the blood. As we have shown already, they are just as useful when we are dealing with a toxic substance which is in the blood and also in the rest of the organism. Of course, this does not hold in the cases where the toxins are fixed irreversibly on tissues other than the blood. In the case of diffusible toxins, by changing the blood of the patient we remove a small part of that poison, but as a new state of equilibrium is obtained between the poisons in the organism and the fresh blood injected, the repeated removal of the blood will enable us to remove completely the toxin from the organism. It would be very interesting to know if other toxins, known or theoretic, could be thus withdrawn from the organism, i. e., radioactive substances or their secondary disintegration products, and thus prevent the medullary aplasia which they cause. In the same line of thought it could be used against acute benzol poisoning.

This technic could also be used to study certain diseases due to as yet unidentified auto-antibodies of the serum, i. e., certain hemolytic anemias, certain types of nephritis. Just as it can replace renal function, this technic could possibly be used to replace the liver function in cases of severe icterus. In general we think that it could be used successfully in all the reversible pathologic conditions in which the main condition for the survival of the patient is that we keep him alive a few days until the organism returns to normal.

(b) *A total substitution of blood enables us to inject in physiologic quantities known and unknown substances* (1) We would like to point out that in many cases where immuno-transfusions have not given the expected results, it has been due to the small quantities used and that in certain cases it was theoretically impossible to hope for any result. On the other hand, we do think that it would be worthwhile if the total blood volume of the patient were replaced by the blood of an immunized donor, and if this operation were repeated many times, the patient would receive a large quantity of antibodies. (2) In many diseases certain substances are absent from the patient's blood and it seems evident that replacement transfusions, especially if repeated, would correct that lack. And if the correction of the lack is noted after the replacement transfusion, it might provide a clue to identifying the cause of the disease.

(c) *Replacement transfusion permits us to study the evolution of a disease with a normal blood* Thus it gives us a means of studying that part of a disease which is due to its action on the tissue cells and that which is due to its modifications of the constituents of the blood or the plasma. It also gives us a means to study the manner and time of evolution of a disease once we have brought back the blood to normal. For example, in a case of lipoid nephrosis if we bring the blood back to normal with replacement transfusions, we can then watch the same disease picture reappear. This technic can also be used to study the survival of red cells, white cells, and platelets.

(d) *Replacement transfusions enable us to realize the condition of parabiosis in man*

Many research groups undoubtedly have had the idea that it would be very interesting to join the circulation of two persons, one sick and one healthy, in order to study the modifications which would be caused in both. Such an operation, however, in practice is impossible in all diseases in which we are not absolutely sure that they are nontransmittable. It would be very important to know what would happen when a patient suffering from a disease of unknown etiology is put in direct circulation with a healthy person. We can use the example of a case of leukemia. There are three possibilities (1) both persons would become leukemic, (2) the leukemic person remains leukemic and the normal person remains normal, (3) the leukemic person returns to normal. This example would also apply to cases of cancer, chronic rheumatism, etc.

As we have already said, such an experiment may be impossible, but repeated replacement transfusions enable us, if not to obtain completely the state of a crossed circulation, at least to approximate it very closely. Of course, we lose all the results on the normal person. However, we can get those results that occur in the sick patient. We could thus find for any disease whether normal blood protects a person by hormones, or antibodies, or other substances which it carries, or whether in certain diseases it has no role at all.

#### SUMMARY

The technic of exchange transfusion in adults and children is given. It differs from that in newborns only by the use of arm or leg veins and of a motor driven pump to withdraw and inject the blood. The use of exchange transfusion in acute toxemia with anuria was tried on the theory that by withdrawing sufficient toxic products, the patient could be tided over the acute phase. Seven patients were thus treated, all with success.

The use of exchange transfusion in leukemia is based on the theory that normal persons have an antileukemic substance in their blood. Thirty-eight cases were treated with the following results: 30 clinical remissions, of which 15 also had peripheral blood remissions, and of these, 6 had complete clinical peripheral blood and marrow remissions. The author concludes by pointing out some possible applications of this technic.

# NITROGEN MUSTARD THERAPY IN HODGKIN'S DISEASE

## ANALYSIS OF FIFTY CONSECUTIVE CASES

By WILLIAM DAMESHEK, M D , LOUIS WEISFUSE, M D , AND TOBIAS STEIN, M D

### INTRODUCTION

MUSTARD gas was first discovered by Ritchie in 1854 and prepared for manufacture by Meyer in 1886. It was first used as a war gas by the Germans at Ypres in the spring of 1915. Five hundred deaths and 14,276 casualties resulted from this initial attack. By the end of the war, there was a total of 400,000 casualties from mustard gas poisoning. The clinical course of these victims was described by Marshall,<sup>1</sup> Mandell and Gibson<sup>2</sup> and others. Pappenheimer and Vance,<sup>3</sup> Warthin and Weller,<sup>4</sup> Lynch et al.<sup>5</sup> studied the effects of mustard gas upon experimental animals. Krumbhaar and Krumbhaar<sup>6</sup> reported upon the hematologic complications.

With the advent of World War II, the Chemical Warfare Service of the United States Army undertook a systematic study of the mustard gases as potential offensive agents. In 1940, these chemicals were submitted, among others, to Drs. L. Goodman and A. Gilman, then at the Yale Medical School, for pharmacologic evaluation. During the course of their investigations they found that following the parenteral administration of an aqueous solution of nitrogen mustard in normal rats, there developed a marked lymphocytopenia together with some degree of anemia and thrombocytopenia. Dr. Thomas Dougherty of the Yale Department of Anatomy studied the effects of the chemical in the spontaneous leukemia and lymphosarcoma of rats. In a number of cases, a marked reduction in the size of abnormal tissues took place.

The possibility then suggested itself that nitrogen mustard might be of some value in the treatment of the leukemias and lymphomata of man. The first patient, a terminal case of lymphosarcoma, was treated at the New Haven Hospital in August 1941 with a dramatic regression of involved glands. One of us (W. D.) was requested to examine the experimental and clinical data obtained in these preliminary studies. Further trial with other patients seemed desirable and a supply of the chemical was given to us for this purpose.

After an initial period terminating with the close of the war, nitrogen mustard was distributed under the auspices of the National Research Council to observers in various parts of the country. Such a cooperative program has made possible a rapid and thorough clinical evaluation of the nitrogen mustards. The historical background, as well as the chemical, pharmacologic, toxicologic, and experi-

From the Ziskind Laboratories (Hematology Section) of the New England Centre Hospital, the U. S. Veterans Hospital, West Roxbury, Massachusetts and the Department of Medicine, Tufts College Medical School, Boston, Mass.

Aided by grants from Merck and Company, Inc., the Charlton Fund and the American Cancer Society (Massachusetts Division).

mental aspects have been reviewed by Gilman and Philips<sup>7</sup> and the initial clinical results were described by Jacobson<sup>8</sup> and Goodman et al.<sup>9</sup> Favorable results have been reported in Hodgkin's disease, lymphosarcoma, leukemia, polycythemia vera,<sup>10-19</sup> mycosis fungoides<sup>20-23</sup> and Boeck's sarcoid.<sup>24</sup> The general results obtained by 120 cooperating physicians are currently being analyzed by Dr. David A. Karnofsky at the Memorial Hospital in New York. Tentative detailed analyses have already been submitted for review.<sup>25-26</sup> Nitrogen mustard has been found to be ineffective in carcinomata (except carcinoma of the lung), Ewing's sarcoma, melanosarcoma and neuroblastoma. The general results obtained have recently been summarized.<sup>27</sup>

Our work with  $\text{HN}_2$  was begun in 1942. We were early impressed with its favorable effects in Hodgkin's disease and in certain cases of lymphosarcoma, although our results with leukemia were disappointing. As our studies continued,

FIG. 1.—CHEMICAL FORMULAE OF SULFUR AND TWO NITROGEN MUSTARDS

the often remarkable therapeutic effects of  $\text{HN}_2$  in Hodgkin's disease became more and more apparent. The present paper deals with a study of the effects of the drug in our first 50 consecutively treated cases of Hodgkin's disease. For the most part, these were moderately and far advanced, oftentimes terminal cases, presenting constitutional symptoms in addition to their local disease.

#### THEORETICAL CONSIDERATIONS

The chemical formulae of the sulfur and nitrogen mustards are shown in Figure 1. Dichloroethyl sulfide is the formula for mustard gas. The most widely used nitrogen mustard is methyl bis (B-chloroethyl) amine, subsequently abbreviated as  $\text{HN}_2$ . In tris (B-chloroethyl) amine, or  $\text{HN}_3$ , the methyl group is replaced by a third chloroethyl group. The sulfur mustards are soluble only in oils whereas the nitrogen mustards are readily soluble in water.

In aqueous solutions, the nitrogen mustards undergo intramolecular cyclization<sup>7</sup> (figure 2). Gilman and Philips<sup>7</sup> have shown that the imino ring possesses an unusual reactivity. It reacts with a great variety of biologically important

groups, i e , alpha amino, sulfhydryl, phenolic, carboxyl, imidazole, imino, inorganic phosphates, chick pepsin peptodase, choline oxidase, etc In the presence of chloride ion, the reaction tends to reverse itself with reformation of the parent amine <sup>28</sup> This probably occurs in the extracellular fluids where the concentration of chloride ion is high Entrance of the parent amine into the cell where there is little, if any, chloride ion to compete with water, results in a rapid transformation with intramolecular cyclization and alkylation of labile groups The speed of this reaction was demonstrated by Karnofsky et al <sup>29</sup> By occluding the circulation to the femoral bone marrow and the small intestine for periods ranging from 2 to 5 minutes, these organs were completely protected from the generalized leukoroxic action of the nitrogen mustards

FIG 2.—INTRAMOLECULAR CYCLIC TRANSFORMATIONS OF METHYL BIS (B CHLOROETHYL) AMINE

The distribution of radioactive sulfur mustard given intravenously to rabbits was studied by Bournsnel et al <sup>30</sup> The concentration of sulfur mustard in the plasma fell rapidly within a period of four hours while the concentration within the red cell layer remained relatively constant Seven per cent of the injected sulfur mustard was excreted into the bile in twenty minutes and 50 per cent was excreted within one hour The amount of radioactive sulfur fixed to the bone-marrow appeared to be of lesser magnitude than that fixed to other organs However, the quantity per gram of total nitrogen was of the same order

Friedenwald and Buschke<sup>31</sup> studied the effect of the nitrogen mustards upon corneal epithelium Cells which were exposed during the active phase of mitosis were unaffected by moderate concentrations of the chemical and went on to complete their division With continued exposure, however, all mitotic figures eventually disappeared The resting stage of the mitotic cycle was the most sensitive period Higher concentrations produced fragmentation of nuclei and abnormal chromosomal patterns which were transmissible through succeeding generations

Various histologic effects of the nitrogen mustards in experimental animals will be discussed below as related to similar effects noted in cases to be reported

## REVIEW OF THE LITERATURE

The dramatic though short-lived effects of the nitrogen mustards in the therapy of Hodgkin's disease were noted early in the course of clinical investigations with the chemical. Jacobson<sup>5</sup> reported the occurrence of remissions in 94 per cent of 120 courses administered to 29 cases. There were 8 failures, 3 of which were terminal and 2 radioresistant. One case had a temporary remission of fever for only three weeks. Four radioresistant cases responded well. Remissions lasted up to ten months.

Craver<sup>11</sup> reported 43 cases of Hodgkin's disease treated at the Memorial Hospital in New York. Constitutional symptoms responded favorably. Partial regression of lymph nodes, liver and spleen followed therapy. Pruritus and bone lesions responded poorly.

Wintrobe and Huguley<sup>10</sup> obtained good improvement in 17 and fair improvement in 5 of 32 treated cases. Fever responded dramatically in almost all cases. Improved well-being and appetite were noted in most cases. Remissions lasted from one to twenty-six months. The average duration of remissions was three months.

Zanes et al.<sup>12</sup> noted that remissions occurred in three types of patients with Hodgkin's disease: (1) patients who were radiosensitive or who had had no previous therapy, (2) patients with severe constitutional symptomatology, (3) radioresistant cases. Patients in the last group were occasionally resensitized to x-ray after a course of nitrogen mustard. Remissions averaged 2.8 months in length.

ApThomas and Collumbine<sup>13</sup> reported 21 treated cases. All improved following their first course. Improvement was noted in 12 of 13 cases who received a second course, and in 2 of 4 cases who received a third course of nitrogen mustard. The response was usually more rapid than previously noted with roentgen therapy. Remissions lasted from two to six months.

Alpert and Peterson<sup>14</sup> reported 8 previously untreated cases, 6 of whom had complete or partial remissions lasting three weeks to four months following HN<sub>2</sub> therapy. Heightened responses were obtained by the co-administration of x-ray therapy.

Talbott<sup>16</sup> obtained no response in 2 of 10 treated cases of Hodgkin's disease. Hettig<sup>16</sup> reported excellent remissions in 2, a partial remission in 1, and slight or no remission in 3 of 6 treated cases. Wilkinson and Fletcher<sup>18</sup> obtained satisfactory remissions in 3 of 4 previously untreated cases lasting up to 17 weeks. Sherry<sup>17</sup> reported remissions lasting from 44 days to 11 months in six cases of Hodgkin's disease.

Taffel<sup>19</sup> reported partial remissions in six cases lasting up to six months.

## MATERIALS AND METHODS

Methyl bis (B chloroethyl) amine\* (HN<sub>2</sub>) was used in the treatment of 50 cases of Hodgkin's disease at the J. H. Pratt Diagnostic Hospital, Boston Dispensary and West Roxbury Veterans Hospital. The diagnosis of Hodgkin's disease was made in almost every instance by biopsy of a suitable enlarged pe-

\* Methyl Bis (B chloroethyl) amine was supplied in generous amounts by the Merck Chemical Company through the cooperation of the National Research Council.

peripheral lymph node. In 2 cases with intraspinal involvement the diagnosis was made in the course of laminectomy and examination of excised tissue. No attempt was made in the analysis of this series of cases to differentiate sharply between various types of disease. We recognize that the growth potentiality of Hodgkin's disease, as of all neoplastic disease, varies considerably from case to case and sometimes in the same case. Our results in the most rapidly growing form of the disease known as Hodgkin's sarcoma were often as striking as with the least malignant types. With study of a larger series of cases in the future it may be possible to analyze more accurately the results of treatment in relation to the histologic picture. In any event the histologic picture of removed tissue was characteristic of the condition known as Hodgkin's disease and showed the histologic features of reticulum cell hyperplasia, increased reticulum, the presence of Reed-Sternberg giant cells and a variable degree of necrosis, eosinophilia and polymorphonuclear infiltration. The cases reported in this paper represent patients consecutively treated between December 1943 and December 1947. There were 29 males and 21 females. Fifteen of the 29 males were treated at the West Roxbury Veterans Hospital. The ages of the patients ranged from 19 to 62 years with a majority of cases below the age of 35. Initially the administration of nitrogen mustard was restricted to radioresistant or terminal cases. In 1946-1947, however, its use was extended to a few radiosensitive and previously untreated cases.

The chemical was packaged in 20 cc ampules, each containing 10 mg. Initially this was dissolved in 10 cc of saline and the required dose injected directly into the vein. Because of the frequent occurrence

TABLE 1—*Immediate Reactions Following 289 Doses of HN<sub>2</sub>*

	per cent
Nausea and vomiting	93.2
Chills	12.4
Fever	6.8

No reaction	6.8

of venous thromboses it became our practice early to inject the material into the rubber tubing of a freely flowing saline infusion. A course of therapy consisted of four to six injections of nitrogen mustard administered on successive or alternate days. An initial dose of 4 to 5 mg. was given on the first day. If this amount was well tolerated, succeeding doses were increased in 1 mg. amounts.

On each visit the presenting symptoms were recorded, the patient examined, and the blood counts obtained. These usually included white blood counts, hemoglobin and reticulocyte levels, platelet counts and a differential count of the white cell cells. Hemoglobin determinations were made with the Cenco hemoglobinometer. Reticulocyte and platelet counts were performed by the method of Dameshek.<sup>22</sup> Stereal bone-marrow punctures were performed prior to therapy in most cases and whenever possible at various intervals following HN<sub>2</sub> administration. The spinous process was often utilized for marrow aspirations in cases studied serially. Serial lymph node aspirations were performed whenever feasible.

## RESULTS

### *Immediate Reactions*

Table 1 lists the immediate reactions following the use of 289 doses of HN<sub>2</sub>. Nausea and vomiting occurred in 93.2 per cent of all cases. This usually began one to three hours after the injection and lasted for two to four hours. The cause of the nausea and vomiting has not been elucidated. It has been attributed to central medullary stimulation and to hemorrhage and necrosis of the gastrointestinal

tract. The marked excretion of the chemical into the bile<sup>30</sup> and subsequently into the second portion of the duodenum may, by causing irritation, be an important factor in the regularity of the occurrence of nausea and vomiting. However, Karnofsky<sup>9</sup> et al. found that the gastrointestinal lesions occurred even when the bile duct was clamped.

There were no reactions in 6.8 per cent of cases. Four of this group responded well making it unlikely that the injected material was inactive. Various attempts were made to reduce the severity of the nausea and vomiting by the co-administration of pyridoxine, morphine and barbiturates.\* Pyridoxine was discontinued because of its possible inactivation by nitrogen mustard.<sup>7</sup> Barbiturates had little value. Morphine appeared to allay much of the apprehension incident to the severe nausea and vomiting. It has been our practice to administer one-eighth grain of morphine sulphate subcutaneously in all hospital cases just before HN<sub>2</sub> administration. Shaking chills were observed in 12.4 per cent of cases. These usually occurred one-half to one hour after HN<sub>2</sub> administration and prior to the onset of nausea and vomiting. Chills recurred with successive doses in 7 cases. Morphine tended to diminish such recurrences. Fever either followed the chills or occurred independently in 6.8 per cent of cases. The exact cause for the pyrogenic reactions is unclear. In rabbits, Boursnel, et al.<sup>36</sup> demonstrated an alteration of serum proteins by mustard gas. These proteins possess different immunologic properties. The presence of such foreign proteins may be etiologic in the occurrence of chills and fever.

Headache was a prominent complaint in two patients who had developed a striking aversion to nitrogen mustard. Dyspnea and cyanosis occurred rarely and generally responded well to sedation.

When HN<sub>2</sub> was injected directly into the vein, thrombosis occurred commonly. The incidence of thrombosis disappeared almost completely with the administration of the chemical into the rubber tubing of a rapidly flowing infusion. Two patients who received tris (B-chloroethyl) amine developed thromboses of all injected veins, even when the material was injected into the rubber tubing.

In 4 cases, HN<sub>2</sub> was administered prophylactically in the form of weekly and biweekly injections in the attempt to maintain a remission induced by a course of medication. The reactions were of such severity that this form of therapy had to be discontinued. The same patients, when treated during an active phase of their disease had much milder reactions. It is possible that the actively proliferating granulomatous tissue present in relapse may selectively absorb the nitrogen mustard. During periods of remissions, however, large quantities of unabsorbed chemical may be available for the production of side reactions.

#### *Type and Duration of Response*

During the first three years of these studies only terminal or radioresistant cases were subjected to therapeutic trial. The results in this group are not as favorable

\* More recently a solution of procaine has been given intravenously immediately following HN administration.

as those obtained in less advanced cases treated during the past year. For purposes of analysis, all cases are however grouped together.

Figure 3 shows the type of response obtained in the first fifty cases of Hodgkin's disease treated with 102 courses of  $\text{HN}_2$ . In 79.4 per cent a complete or partial response to therapy occurred. In 20.6 per cent, there was no response.

The duration of the response ranged from 17 to 331 days\* (figure 4). Remissions lasting less than fifty days were noted in 41.7 per cent, 35.2 per cent developed good responses lasting from 50 to 331 days.

FIG. 3.—TYPE OF RESPONSE OBTAINED FOLLOWING 102 COURSES OF  $\text{HN}_2$  IN 50 CASES OF HODGKIN'S DISEASE

Twenty-three patients received a single course of  $\text{HN}_2$ , 11 patients received 2 courses, 9, 3 courses, 4, 4 courses, 2, 5 courses, and 1, 8 courses of  $\text{HN}_2$ . The general results obtained with successive courses of  $\text{HN}_2$  are roughly comparable to the composite results for all courses, with the same proportion of successes and failures. The duration of the response obtained in sixteen patients who received multiple courses with varying dosage schedules was approximately proportional to the total dose administered.

Thirty-one patients in this series were regarded as having become resistant to x-ray therapy and in 13 of these, all of whom appeared to be running a progressively downhill course, good remissions following therapy were obtained. Some of the most spectacular results were seen in cases that were virtually moribund on

\* The results as reported in this paper are based on findings ending December 15, 1947.

admission (cases 1, 23 and 28) There can be no doubt that many patients of this group have had a moderate prolongation of their life span, as well as a more comfortable existence after having become completely resistant to further x-ray therapy Nitrogen mustard was particularly useful in 5 cases with severe x-ray dermatitis

Nine patients failed to show any response following the initial and subsequent courses of nitrogen mustard therapy

In 7 patients, roentgen therapy was given just before the administration of nitrogen mustard In 4 of this group (cases 10, 21, 28 and 40), there was definite prolongation of the length of the remission In 8 cases, x-ray therapy was given

FIG 4—DURATION OF RESPONSES FOLLOWING 91 COURSES OF  $\text{HN}_2$  IN 50 CASES OF HODGKIN'S DISEASE

following the administration of nitrogen mustard In 3 of these cases residual lymphoid organs regressed with unusual rapidity when x-ray therapy was given

Four cases received  $\text{HN}_2$  as their sole initial therapy The remissions lasted from 36 to 120 days in 3 cases Case 9 received three courses of nitrogen mustard which resulted in partial remissions lasting 36, 30 and 51 days respectively The latter course had been combined with roentgen therapy Case 49, who developed a severe hemorrhagic complication due to thrombocytopenia has nevertheless had an excellent remission which had continued to the time of this writing

Case 31, received combined  $\text{HN}_2$ -roentgen therapy following which he had a complete remission lasting 210 days

The number of patients given  $\text{HN}_2$  as the first therapeutic procedure is too small to permit statistical evaluation It appears, however, that the remissions obtained are of much shorter duration than is usually the case following roentgen therapy

Similar results were reported by Alpert and Peterson<sup>14</sup> The remissions appear to be definitely longer if combined  $\text{HN}_2$  and x-ray therapy is administered

## EFFECTS OF NITROGEN MUSTARD THERAPY ON CLINICAL MANIFESTATIONS

*Systemic Manifestations*

A majority of the patients in this series had the characteristic constitutional symptomatology of severe, long standing Hodgkin's disease, i.e., malaise, case

TABLE 2.—*Response of Signs and Symptoms Following HN<sub>2</sub> Therapy (50 cases of Hodgkin's Disease)*

Signs and Symptoms	Number of Adminis- trations	Percentage Completely Relieved	Percentage Partially relieved	Percentage Unrelieved
<b>A. Constitutional symptoms</b>

of fatigability, anorexia, fever, night sweats, pruritus and chills. Fatigability and anorexia were relieved (completely or partially) in 82.4 and 87.1 per cent of cases respectively (table 2.)

Following a course of nitrogen mustard therapy and after the immediate reaction had subsided, there usually occurred a marked upsurge in vitality and well-

being Those patients who had previously received roentgen therapy usually commented upon the greater subjective improvement which followed the administration of nitrogen mustard

Seven patients were treated with nitrogen mustard shortly after the recognition of their disease In 2 cases (21 and 40) this was administered after a partially effective or ineffectual course of roentgen therapy Single courses of  $\text{HN}_2$  resulted in excellent remissions lasting respectively 331 and 169 days and continuing to the time of this writing Case 21 illustrates a striking response in constitutional symptoms and a prolonged remission

#### CASE 21 (FIGURE 5)

*P D C* A 36 year old white male began to notice easy fatigability weakness and marked weight loss in 1944 In January 1946 weakness and fatigability became much more pronounced In September 1946 he was found to have continuous fever A gnawing sensation in the mid abdomen was relieved by food and medication He was admitted in October 1946 to the West Roxbury Veterans Hospital

*Physical Examination* Temperature 99.4 F The patient was a well developed rather well nourished white male His voice was hoarse The eyes were slightly protuberant The right lobe of the thyroid was more readily palpable than the left The chest was clear and resonant throughout A grade II systolic murmur was heard just to the left of the sternum and in the fourth interspace The heart was otherwise negative The liver and spleen were not felt There were bean sized axillary (right) lymph nodes

*Laboratory Data* Blood counts leukocytes 18 800 erythrocytes 3 600 000 hemoglobin 11.1 Gm differential polymorphonuclear neutrophils 80 per cent monocytes 5 per cent lymphocytes 15 per cent The urine was negative Blood sedimentation rate was 55 mm per hour, Mazzini test was negative Sputum was negative for tubercle bacilli Basal metabolic rate was plus 34.5 per cent A roentgenogram of the chest showed evidence of mediastinal lymphadenopathy Biopsy of an enlarged axillary node revealed the presence of Hodgkin's granuloma

*Course* The patient ran a febrile course with temperature elevations up to 101.4 F Beginning October 31 1946 the patient was given 18 roentgen treatments over the anterior and posterior chest and to the right axilla However he continued to run a low grade fever and to lose weight Several right axillary nodes were still palpable Repeat roentgenograms of the chest showed a complete reduction in the size of the right upper mediastinal mass A flat plate of the abdomen at this time revealed an enlarged spleen extending down to about two inches above the iliac crest On January 4 1947 a course of nitrogen mustard therapy was begun consisting of 4 5 6 and 7 mg doses administered on successive days Nausea and vomiting occurred two hours after each administration and lasted from one half hour to three hours The fever subsided promptly Shortly after the nitrogen mustard therapy there followed a reduction in the white blood count from 18 000 to 6600

The patient developed a marked improvement in his appetite and gained about 60 pounds in weight He had a remarkable upsurge in strength and sense of well being Lymphadenopathy disappeared entirely and the spleen regressed completely He was then observed at regular intervals in the outpatient department and continued in an excellent state of remission to the time of writing almost a year later

*Fever*, which was a presenting complaint in 30 cases, was completely relieved in 58.7 per cent following  $\text{HN}_2$  treatment (figure 6)  $\text{HN}_2$  appeared to be less effective in 13 terminal patients who showed the typical Pel-Ebstein type of relapsing fever Two of these cases had responded well to a previous course of therapy Cases 19 and 24 had associated infections, i.e., a chronically draining bronchopleural fistula, and an ascending urinary tract infection respectively The infections were not affected by the  $\text{HN}_2$  treatment

Severe night sweats were relieved in 84 per cent of cases Of 4 cases, in which night

sweats did not respond to  $\text{HN}_2$  therapy, 3 were terminal, and case 19 noted above had a chronic infectious process

Pruritus was present in 10 cases prior to nitrogen mustard therapy. Improvement followed in 73.3 per cent. The pruritus was of such intensity in case 38 that the patient forcefully removed all toenails and produced deep excoriations of the skin.

FIG. 5.—EFFECTS OF  $\text{HN}_2$  IN PATIENT (CASE 21) WHO HAD DEVELOPED RESISTANCE TO X-RAY THERAPY. The constitutional symptoms fever, mediastinal adenopathy, generalized lymphadenopathy, and splenomegaly were promptly relieved following  $\text{HN}_2$  therapy.

Roentgen therapy could no longer be administered because of severe x-ray dermatitis. Considerable relief and healing of the excoriations followed each of two courses. Four terminal cases showed no response.

Chills were present in 5 patients, 4 of whom responded well to therapy. In one case there was a progressively downhill course.

### Lymphoid Involvement

**Lymphadenopathy.** Regression of enlarged glands occurred in 70.2 per cent of the cases. In a few patients this was noted as early as twelve hours after the injection of the first dose of nitrogen mustard. Rarely, slight initial enlargement preceded subsequent regression of glands. Twenty-eight of the 44 patients with lymphadenopathy were referred to us for nitrogen mustard therapy because of their radio-

resistant state, of this group, 60.3 per cent showed a complete or partial response. The following case is described in detail to illustrate the response obtained in a patient with a fluctuant supraclavicular mass and a superimposed severe radio-dermatitis.

## CASE 39

M V, a 25 year old white female noted the onset of left supraclavicular adenopathy in December 1945. A biopsy taken in March 1946 revealed the presence of Hodgkin's disease. Roentgen therapy was

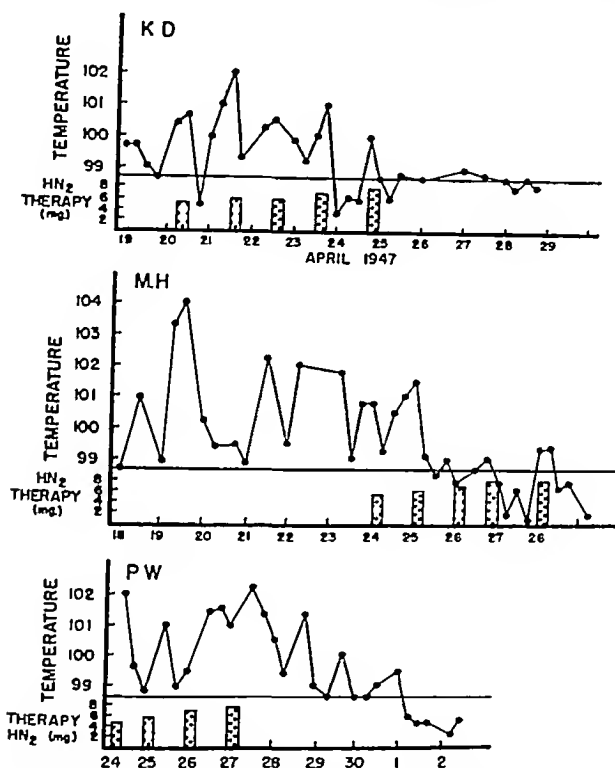

FIG. 6—EFFECT OF HN<sub>2</sub> IN REDUCING FEVER IN 3 CASES OF SEVERE HODGKIN'S DISEASE

administered in the left supraclavicular axillary and mediastinal areas with gradual improvement. Adenopathy recurred in October 1946 and continued to increase despite intensive roentgen therapy. The left supraclavicular mass became fluctuant and soon broke through the superimposed skin which showed evidence of a severe radiodermatitis. The roentgenologist referred her for nitrogen mustard therapy in May 1947.

**Physical Examination.** The patient showed pallor. She presented a large hard but superficially fluctuant left supraclavicular mass 12 cm in diameter superimposed by a deeply pigmented area of skin (fig. 7a). There was a number of smaller cervical, right supraclavicular and left axillary glands. The spleen and liver were not enlarged.

**Laboratory Data.** Blood counts: Leukocytes 20,050; erythrocytes 3,630,000; hemoglobin 11.0 Gm; reticulocytes 0.9 per cent; platelets 785,500; differential count: polymorphonuclear neutrophils 57

per cent, band forms 17 per cent monocytes 8 per cent lymphocytes, 13 per cent Bone marrow differential polymorphonuclear neutrophils, 25 6 per cent band forms 14 2 per cent, metamyelocytes, 19 2 per cent, myelocytes 15 8 per cent, promyelocytes 1 2 per cent myeloblasts, 0 5 per cent reticulum cells 0 2 per cent plasma cells 2 0 per cent megakaryocytes plentiful erythrocyte granulocyte ratio 1 7 The urine was negative The Hinton test was negative The blood sedimentation rate was 72 mm per hour Roentgenograms of the chest showed left supraclavicular and mediastinal masses

*Course* The left supraclavicular mass was incised and drained The patient was then started on a course of HN consisting of 5, 5 6, 7 and 8 mg administered on successive days Each dose was followed by rather severe nausea and vomiting The wound healed rapidly and all glandular adenopathy subsided completely leaving only a small area of induration in the left supraclavicular region (fig 7b) A repeat roentgenogram of the chest showed reduction in the size of the mediastinal and supraclavicular masses The remission lasted approximately three months when supraclavicular and axillary adenopathy recurred The patient received a second course of HN consisting of 5 6 7 and 8 mg administered on alternate days There was again regression of all the glands

Eight cases failed to show any regression of lymph nodes following HN<sub>2</sub> therapy Case 5 had had two previously successful remissions following HN<sub>2</sub> and lasting 74 and 56 days respectively Four patients showed no response to the initial course of the therapy

Three patients with HN<sub>2</sub> resistant glandular enlargements responded unusually well to roentgen therapy given shortly after administration of one course of HN therapy Case 9 is described in detail, and case 14, is presented briefly

#### CASE 9

*V K* a 25 year old white female was first seen in September 1946 She presented a six month history of anorexia weakness fatigability weight loss fever and cervical adenopathy Biopsy of an enlarged gland revealed Hodgkin's disease probably of the sarcoma type

*Physical Examination* The patient showed moderate pallor and marked weight loss She had a right Horner's syndrome There was generalized adenopathy Supracardiac dullness was 8 cms in diameter The spleen was three finger's breadth below the left costal margin

*Laboratory Data* Leukocytes 10 800 erythrocytes 3 810 000 hemoglobin 7 6 Gm reticulocytes 0 5 per cent platelets 663 940 differential polymorphonuclear neutrophils 79 per cent band forms, 10 per cent monocytes 4 per cent lymphocytes, 7 per cent Bone marrow differential polymorphonuclear neutrophils 21 5 per cent band forms 29 5 per cent metamyelocytes 21 0 per cent myelocytes 10 5 per cent promyelocytes 0 5 per cent myeloblasts 0 5 per cent plasma cells 0 3 per cent reticulum cells 0 3 per cent reticulum cells 2 0 per cent megakaryocytes plentiful, erythrocyte granulocyte ratio 1/3

The urine was negative The Hinton test was negative Roentgenograms of the chest showed marked mediastinal widening (fig 8a)

*Course* The patient received 4 mg of HN on September 25 1946 Three-quarters of an hour later she became moderately dyspneic and cyanotic This responded gradually to sedation She received two additional doses consisting of 4 and 6 mg on September 29 and 30 respectively These were followed by the usual reactions of nausea and vomiting A roentgenogram of the chest taken five days after the completion of nitrogen mustard therapy showed marked regression of the mediastinal mass Further reduction was noted seven days later (fig 8b) There was complete regression of all peripheral glands

The patient had a remission which lasted 36 days Following this she developed recurrent cervical adenopathy A second course of HN consisting of 4 5 5 6 and 6 mg was administered on alternate days beginning November 4 1946 Enlarged glands regressed completely Thirty three days later the patient noted the onset of anorexia weight loss left cervical and bilateral axillary glands and a walnut sized parasternal mass in the second interspace on the right The spleen descended one finger's breadth below the left costal margin A third course of HN consisting of 4 5 6 and 7 mg was administered on alternate days beginning January 6 1946 A chill followed the second third and fourth doses within

FIG 7—RESPONSE OF RADIORESISTANT SUPRACLAVICULAR GLAND WITH SUPERIMPOSED BROKEN DOWN  
PIGMENTED SKIN EXUDING SERO-PURULENT MATTER (CASE 39)

(a) PRIOR TO  $\text{HN}_2$  THERAPY

FIG 7—(b) AFTER COMPLETION OF COURSE OF  $\text{HN}_2$  THERAPY

FIG 8—RESPONSE OF MEDIASTINAL ADENOPATHY FOLLOWING  $\text{HN}_2$  THERAPY (CASE 9)  
(a) PRIOR TO FIRST COURSE OF THERAPY

FIG 8—(b) SAME PATIENTS TWELVE DAYS AFTER COMPLETION OF FIRST COURSE OF THERAPY

one half three-quarters and two hours respectively. The usual reactions of nausea and vomiting followed each dose. The patient had a marked upsurge in well being and gained five pounds in weight. Glandular adenopathies regressed approximately 25 per cent. Roentgen therapy was then administered to the parasternal and left supraclavicular areas (1200 r each). Rapid resolution of residual glands occurred. This remission lasted sixty-one days. Further nitrogen mustard was refused.

#### CASE 14

This patient a long standing example of Hodgkin's disease with the presenting complaint of severe constipation showed a very large mass in the left lower quadrant of the abdomen dipping into the pelvis. A course of nitrogen mustard therapy was completely ineffectual. Roentgen therapy was then given to both the left lower quadrant (600 r) and the right lower quadrant (400 r) and was followed by rapid resolution of the pelvic masses and a dramatic relief of constipation.

*Splenomegaly* Seventy-one and seven-tenths per cent of the cases with splenomegaly showed complete or partial regression of the enlarged spleen following  $\text{HN}_2$  therapy. This corresponds roughly to the results obtained with lymphadenopathies. The striking affinity of nitrogen mustard for the various lymphoid organs was noted by Pappenheimer and Vance<sup>3</sup> and by Graef et al.<sup>17</sup> Atrophy of lymph nodes, spleen and thymus has been demonstrated in normal mice, rats, rabbits, dogs, chickens and pigeons following the administration of nitrogen mustard.

*Edema* Edema due to pressure by enlarged lymph nodes or to lymphatic obstruction was present in 12 cases prior to the initiation of nitrogen mustard therapy. Two patients had edema of the lateral half of the breast, secondary to enlarged axillary nodes. Case 12 presented an orange-sized right axillary mass with edema of the lateral half of the right breast. A partial response followed the administration of 26 mg. of  $\text{HN}_2$ . Roentgen therapy then brought about rapid and complete regression of the axillary glands as well as edema. Case 2 had very large axillary masses and edema of both breasts. A partial remission lasting one month was induced by the first course of nitrogen mustard. Two subsequent courses, however, were without effect.

Gross edema of the lower extremities was present in four patients.

#### CASE 30

*W J O*, a 44 year old white male was first seen in March 1947. Six years previously he had noted the presence of a large mass in the left inguinal region. A biopsy revealed Hodgkin's disease. Intensive roentgen therapy induced a complete regression. Further roentgen therapy was administered as needed with recurrent glandular adenopathies. Increasing radioresistance was noted. Six months prior to admission the patient developed massive edema of the left lower extremity extending to the lumbar area. Roentgen therapy was initially effective in reducing the edema. Three months prior to admission the patient developed extreme edema of the right lower extremity and scrotum. Roentgen therapy was ineffectual.

*Physical Examination* The patient had massive edema amounting to elephantiasis of both lower extremities and the scrotum. There was an x-ray dermatitis of the left inguinal, gluteal and lumbar areas. The liver was felt four fingers breadth below the right costal margin and the spleen three fingers breadth below the left costal margin.

*Course* The patient received three daily injections of  $\text{HN}_2$ . Within ten days the edema had completely subsided. The patient remained well for three weeks when he suddenly developed a severe pain in the left groin radiating to the hip and small of back. The edema of the left lower extremity recurred. Three days later, the patient had a sudden massive gastrointestinal hemorrhage. He rapidly lapsed into shock and died twelve hours later.

*Postmortem* At autopsy there was a fistulous communication between the p.l.v.s the retroperitoneal lymph nodes and rectosigmoid. The descending colon contained much freshly coagulated blood. Both ureters were compressed by a large retroperitoneal mass producing bilateral hydronephroses and hydrocephroses. There were large nodes in both inguinal regions with compression of the femoral artery and vein on the left.

In another patient (Case 23), massive ascites and marked edema of both lower extremities was present. The energetic use of paracentesis, transfusions, plasma, albumin and  $\text{HN}_2$  therapy brought about a marked reduction of the edema and ascites and a well-defined remission.

Edema of the upper extremities was present in 2 cases. Case 8, with scar tissue in the left supraclavicular and axillary nodes, was treated with  $\text{HN}_2$ , which brought about an approximately 30 per cent reduction in the edema. Two subsequent courses were however, completely ineffectual.

Three patients had edema suggesting superior vena caval obstruction. These will be discussed below, under mediastinal involvement.

As noted above, edema may be due to lymphatic or venous obstruction, pressure from enlarged glands, or by scar tissue. When due to enlarged glands, nitrogen mustard was found to be moderately effective. When due to scar tissue little or no effect was obtained. It is probable that  $\text{HN}_2$  is far less productive of scar tissue than is roentgen therapy.

### *Mediastinal Involvement*

*Roentgen Changes* X-rays of the chest were performed routinely in all cases. Twenty-one cases showed radiologic evidence of pulmonary or mediastinal involvement. In 7, there was no associated symptomatology. The response of such asymptomatic mediastinal adenopathy to nitrogen mustard therapy is shown in figure 8.

Twelve patients had symptoms referable to their pulmonary pathology, i.e., cough, dyspnea, hoarseness and dysphagia. This group usually had extensive mediastinal involvement. Eleven cases had been previously declared radioresistant. The response to the  $\text{HN}_2$  therapy was only moderately effective in this group. The following case illustrates a partial response to  $\text{HN}_2$  therapy and a better response to combined  $\text{HN}_2$  and roentgen therapy.

#### CASE 25 (FIGURE 9)

*K. D.*, a 37 year old white housewife was the first seen on February 3, 1947. Five and one half years ago she noted the onset of right cervical adenopathy and upon roentgenographic examination of the chest was shown to have a mediastinal mass. A biopsy revealed the presence of Hodgkin's disease. Roentgen therapy was then administered to the cervical and mediastinal areas with prompt improvement. During the following three years the patient received five courses of roentgen therapy each of which induced a short remission. In March 1947 an episode of severe cough, chills, fever (103 F), dyspnea and fatigability developed.

*Physical Examination.* The patient had a marked radio-dermatitis over the anterior and posterior chest. No adenopathy could be made out. Supracardiac dullness was 17 cm. in diameter. Bronchial breath sounds were present over the left apex. The liver and spleen were not palpable.

*Laboratory Data* Blood counts: leukocytes 8,500, erythrocytes 4,170,000, hemoglobin 12.1 Gm, reticulocytes 1.6 per cent, platelets 638,880, differential polymorphonuclear neutrophils 65 per cent, band forms 12 per cent, eosinophiles 2 per cent, basophiles 1 per cent, monocytes 6 per cent, lympho-

cytes, 14 per cent. The urine was negative. The Hinton test was negative. Roentgenograms of the chest showed extensive anterior mediastinal enlargement (fig. 9) and bilateral infiltration of the lung.

*Course.* The patient was started on a course of HN consisting of 4, 5, 6, and 7 mg administered on alternate days beginning February 3, 1947. Shaking chills occurred two hours after the first, second and fourth injections. The usual reactions of nausea and vomiting followed. The patient experienced a marked reduction of cough and dyspnea as well as a striking improvement in vitality. The remission lasted for about three weeks when in March 1947 she had another episode of fever (104 F) cough and dyspnea. A similar episode occurred one month later. A roentgenogram of the chest revealed a large mediastinal mass occupying almost the entire upper chest. A second course of HN<sub>2</sub> was instituted on April 20, 1947 and consisted of daily injections of 6, 6, 6, 7 and 8 mg. The usual reactions of nausea and vomiting occurred. The fever subsided gradually. Roentgen therapy to the mediastinum in a total dosage of 1200

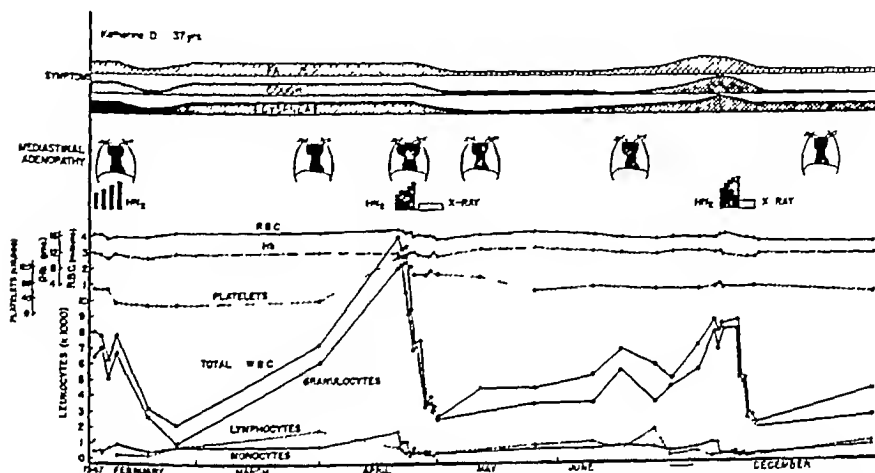

FIG. 9—EFFECTS OF NITROGEN MUSTARD IN PATIENT WITH MASSIVE MEDIASTINAL INVOLVEMENT WHO HAD BECOME MARKEDLY RADIORESISTANT (CASE 25). A distinct, although temporary response took place with the use of HN<sub>2</sub> but best effects were obtained when HN<sub>2</sub> was given first and then followed by x-ray therapy.

r was then given. A marked improvement again occurred with considerable relief of cough, dyspnea and fatigability. Roentgenograms of the chest showed marked regression in the size of the mediastinal mass. A third course of HN<sub>2</sub> was instituted on September 30, 1947 and consisted of daily injections of 5, 6, 7 and 8 mg. Roentgen therapy was also given through axillary portals: 450 r to the right axilla and 525 r to the left axilla. The patient showed an improvement in well-being but no further change in the size of the mediastinal mass was noted.

There can be no question that combined HN<sub>2</sub> and x-ray therapy was productive in this patient of more prolonged and effective remissions than HN<sub>2</sub> alone. A symptomatic response occurred following the third course although no further roentgenographic change could be noted.

*Cough.* Cough was a presenting symptom in 13 cases. Complete or partial improvement followed nitrogen mustard therapy in 50 per cent of the cases. In the other half, no response occurred and the patients ran a progressively downhill course.

*Dyspnea.* Dyspnea was notable in 15 cases prior to therapy. Cases 18, 42, and 43

showed no mediastinal involvement but had extensive and generalized involvement with Hodgkin's disease. Case 23 had massive ascites. Cases 22 and 50 had a massive hydrothorax as well as ascites. The results obtained within this group were generally unsatisfactory (table 2).

*Hoarseness and Dysphagia* All cases displaying these symptoms represented far advanced radioresistant cases. No improvement was noted following  $\text{HN}_2$  therapy.

*Superior Vena Cava Syndrome* Two patients showed signs of superior vena cava obstruction. Case 11 developed puffiness of the eyelids, suffusion of the conjunctivae, and swelling of the cheek during his course of  $\text{HN}_2$ . This gradually subsided as did the hilar adenopathy. Case 1 is described in detail (previously reported).<sup>9</sup>

#### CASE 1

*L W*, a 33 year old housewife, was first seen in 1941 because of axillary adenopathy. Her father had died of Hodgkin's disease and her mother of polycythemia vera. A biopsy revealed the presence of Hodgkin's disease. In rapid succession nodes appeared in the axillae, neck, and mediastinum. Roentgen therapy was given with excellent results initially; subsequent results were poor. In the summer of 1942, dyspnea and cough developed and a thoracentesis was required for the pleural effusion. Complete motor and sensory paralysis of the right arm appeared in the spring of 1943 and the limb gradually increased threefold in size. Cough, weakness, and dyspnea became worse. Lymph node masses increased and in the fall of 1943 the patient was bed ridden and failed to respond to further x-ray treatment.

*Physical Examination.* The patient was extremely ill and very cyanotic with a shallow dry cough and gasping respirations. The face and neck were greatly swollen and distorted and there was pitting edema over the upper thorax. The breasts were large and edematous. The right arm was greatly swollen and completely paralyzed. The left side of the neck bulged with a hard, irregular mass extending into the supraclavicular fossa. Both axillae were occupied by hard, irregular masses of nodes extending on the right side to the lower chest. The percussion note was dull to flat over both thoraces and the breath sounds were diminished. There was no enlargement of the spleen or liver and no inguinal adenopathy. The temperature ranged from 98 to 103 F and the pulse from 100 to 140 per minute.

*Laboratory Data.* Blood counts: leukocytes 8500, erythrocytes 3,910,000, hemoglobin 86 per cent, differential polymorphonuclear neutrophils 73 per cent, eosinophils 11 per cent, monocytes 13 per cent, lymphocytes 3 per cent. The Hinton test was negative. The urine was negative. The blood sedimentation rate was 40 mm per hour. Roentgen examination disclosed no mediastinal mass but decided infiltration of the lower two-thirds of both lung fields was present.

*Course.* On December 7, 1943, the patient was started on a course of tris (B-chloroethyl)amine administered on alternate days for four doses (11 mg per kilogram of body weight). This was injected by the direct syringe method. Improvement started after the second dose and continued over a period of two weeks. The patient felt much better; the fever and cyanosis disappeared; the dyspnea being improved and cough improved. The lymph node masses shrank 60 to 70 per cent; the breasts became smaller; the disfiguring edema of the face and neck receded entirely and the hugely swollen arm returned almost to normal size. Roentgenograms of the chest revealed no change in pulmonary infiltration.

The dramatic therapeutic remission persisted four weeks when it was interrupted by a sudden severe attack of pulmonary edema which quickly resulted in death. Postmortem examination was not obtained.

The results obtained in cases with extensive mediastinal involvement were on the whole not as satisfactory as those obtained with lesser degrees of mediastinal involvement. However, a more comfortable existence as well as a moderate prolongation of life was achieved with nitrogen mustard therapy. In patients who had been previously subjected to intensive roentgen therapy the resultant fibrosis within and around the mediastinal tumor mass may well occlude the vascular

avenues of approach. With little or no previous Roentgen therapy mediastinal tumors appeared to respond more satisfactorily.

### *Hepatic Involvement*

**Hepatomegaly** Hepatomegaly was present in 15 cases. Thirty-six and six-tenths per cent showed regression following  $\text{HN}_2$  therapy. Those who failed to respond were radioresistant terminal cases. Individuals with lesser degrees of hepatomegaly appeared to respond satisfactorily.

**Jaundice** In four cases hepatic enlargement was associated with jaundice. Two responded well while the other two showed no signs of improvement and in fact became worse following therapy. The following case is illustrative of a possible aggravation of liver dysfunction following  $\text{HN}_2$  therapy.

### CASE 35

**H. M.**, a 45 year old white male was first seen on April 16, 1947. Eight months prior to admission he noted the presence of a mass in the right cervical region which gradually increased in size until it filled the entire right side of the neck. He developed marked fatigability, night sweats and pruritus. A biopsy revealed the presence of Hodgkin's disease. Roentgen therapy produced a short remission. Subsequent roentgen therapy was completely ineffectual and the patient became progressively more disabled with severe night sweats and fever.

**Physical Examination** Temperature 104 F, pulse 126 per minute, respirations, 32 per minute. The sclerae were markedly icteric. There was no adenopathy. The liver descended one finger's breadth and the spleen two fingers' breadth below the right and left costal margins respectively.

**Laboratory Data** Blood counts: leukocytes 6100, erythrocytes 3,010,000, hemoglobin 9.3 Gm. differential polymorphonuclear neutrophils 45 per cent, band forms 21 per cent, monocytes 16 per cent, lymphocytes 18 per cent. Bone marrow: hyperplastic differential polymorphonuclear leukocytes 27.5 per cent, band forms 30.5 per cent, metamyelocytes 24.5 per cent, myelocytes 12.5 per cent, promyelocytes 1.5 per cent, plasma cells 2.5 per cent, reticulum cells 1.6 per cent, erythrocyte granulocyte ratio 1:2.5. The urine showed four plus albumin and four plus urobilinogen. The blood sedimentation rate was 125 mm. per hour. The total serum bilirubin was 2.5 mg. per cent. A roentgenogram of the chest revealed hilar adenopathy and increased markings extending down to the right lower lobe.

**Course** On April 17, 1947, the patient was started on a course of  $\text{HN}_2$  consisting of 6, 7, 8 and 6 mg administered on successive days. The first dose was followed within one half hour by a chill and within two hours by moderate nausea and vomiting. There were no reactions following the last three doses. Icterus was more intense on the third day of therapy. The patient became increasingly stuporous, lapsed into coma and died nine days after the institution of therapy.

**Postmortem Examination** There was a well-defined icterus of the skin and sclerae. The spleen and liver weighed 475 and 2240 grams respectively. There was extensive granulomatous infiltration within these organs as well as the tracheo-bronchial, paraortic and retroperitoneal nodes. Partial compression of the common bile duct resulted from an enlarged node at the head of the pancreas. Microscopic examination revealed numerous foci of necrosis in the liver with swelling and vacuolization of the reticulo-endothelial cells and marked hypoplasia of the bone marrow.

The progressively downhill course of this patient was probably accelerated by the administration of  $\text{HN}_2$  in the face of definite icterus. It is probable that the miliary necroses of the liver and hypoplasia of the bone marrow could be directly attributed to  $\text{HN}_2$  therapy.

**Ascites** Ascites was present in three cases. Partial relief was effected in two cases. Case 5, radioresistant, had marked ascites, pleural effusion, dyspnea, fever, anorexia and malaise.  $\text{HN}_2$  therapy and other supportive measures brought about a

satisfactory partial remission. Case 23 is illustrative of a partial response to vigorous therapeutic measures including HN<sub>2</sub>.

#### CASE 23

*V C* a 24 year old white female was first seen on January 7 1947. A diagnosis of Hodgkin's disease had been made two and one-half years prior to admission after a six month period of fever, sweats, hoarseness, adenopathy and splenomegaly. Roentgen therapy was only partially effective in reducing glandular enlargement. She had herpes zoster one year prior to admission. During the past three months she had developed progressive fatigue, anorexia, dyspnea, ascites and edema of the lower extremities.

The patient had a marked pancytopenia and hypoproteinemia and required frequent transfusions.

*Physical Examination* The patient was markedly emaciated. She had a right Horner's syndrome. There was generalized shorty adenopathy, marked ascites, hepatosplenomegaly and pitting edema of the lower extremities.

*Laboratory Data* Blood counts: leukocytes 2000, erythrocytes, 3,380,000, hemoglobin 56 per cent, platelets 267,020, reticulocytes 1.6 per cent, differential: polymorphonuclear neutrophils 32 per cent, band form, 26 per cent, metamyelocytes 3 per cent, monocytes 31 per cent, lymphocytes 7 per cent. Bone marrow hypercellular, differential: polymorphonuclear neutrophils 6.8 per cent, band forms 16.4 per cent, metamyelocytes 23.8 per cent, myelocytes 30.0 per cent, promyelocytes 1.4 per cent, myeloblasts 4.0 per cent, eosinophils 3.6 per cent, lymphocytes 0.4 per cent, plasma cells 0.2 per cent, reticulum cells 5.2 per cent, megakaryocytes plentiful, erythrocyte: granulocyte ratio 1:1. The urine showed two plus albumin. The Hinton test was negative. The total proteins were 4.4 gms. per cent, albumin 3.0 Gm., globulin 1.4 Gm.

*Course* The patient received five doses of HN<sub>2</sub> consisting of 3, 4, 5, 6 and 5 mg. administered on alternate days beginning January 11, 1947. She had moderate nausea and vomiting starting two hours after each injection and lasting 3 to 4 hours. The Horner's syndrome disappeared completely. Adenopathy and hepatosplenomegaly regressed partially. The patient received numerous supportive measures including intravenous blood, plasma, albumin, vitamins and paracentesis. The serum protein rose to 5.1 Gm. per cent. Leukocytes fell to 900 and penicillin was administered. The platelets rose to 410,000. Thirteen days after the initiation of therapy the bone marrow showed a marked decrease in cellularity and a shift of granulocytic elements to more mature forms. Improved appetite and general well being continued for about four months. In May 1947 she developed jaundice and severe epistaxis. A second course of HN<sub>2</sub> was instituted but ascites recurred and the patient went progressively downhill and died. Postmortem examination was not obtained.

This patient appeared to be in a terminal state upon admission and HN<sub>2</sub> was administered only after considerable hesitation especially since marked leukopenia was also present. However, following therapy the patient had a four month remission and in fact showed partial improvement of her pancytopenia. Rosenthal<sup>38</sup> has described the use of nitrogen mustard therapy with splenectomy in those cases having severe leukopenia. Splenectomy was found to be effective in raising the leukocyte level. Remissions tended to be of longer duration with this drastic procedure and the leukocyte count was not lowered. Experience with this form of combined therapy is as yet too limited to permit evaluation.

Case 22 showed ascites, hepatosplenomegaly, hydrothorax and fever.

Patients displaying ascites and extensive hepatic involvement have, on the whole, responded poorly to HN<sub>2</sub>. Boursnell, et al.<sup>39</sup> demonstrated the excretion of as much as 50 per cent of intravenously injected sulfur mustard into the bile of rabbits within one hour. With diffuse granulomatous infiltration biliary excretion is undoubtedly impaired, and the avenue of approach to involved areas obstructed. Roentgen therapy may be of some value in such cases.

## *Neurologic Involvement*

### *Intraspinal*

Intraspinal involvement has been attributed to the following pathogenetic mechanisms (1) extension from retroperitoneal and posterior mediastinal granulomatous tissue via the intervertebral foramina into the epidural space, (2) extension from an involved vertebra, or compression from collapsed vertebral bodies, (3) mechanical obstruction of blood vessels within the intervertebral foramina or just outside the cord, causing diffuse myelomalacia, and (4) toxic myelitis.<sup>34-36</sup> Pressure from lesions extending from involved vertebrae was present in one treated case (case 20) and in one untreated case (case 6). In the other cases, there was probable extension via the intervertebral foramina. Thromboses of blood vessels may well have been a contributing factor in some cases.

**Spastic Paraplegia** During the course of our observations, 5 patients developed spastic paraplegias. In 3 cases this developed terminally and we did not have the opportunity to treat them with nitrogen mustard. The other 2 cases are described in detail. The results of treatment with HN<sub>2</sub> were of only partial and temporary value.

### CASE 8

**G. S.** a 31 year old housewife was first seen in July 1946. She had developed cough, pruritus, cervical and axillary adenopathy and splenomegaly in 1944. Roentgen therapy induced a six year remission. In January 1946 she noted the onset of painful swelling of the left arm and breast. Cough, dyspnea and fatigue were present. In March 1946 Roentgenograms of the chest showed a massive hydrothorax and bilateral hilar adenopathy. Two thoracotomies brought about considerable relief of dyspnea. This was followed by roentgen therapy to the mediastinum with complete resorption of the left thoracic fluid and regression of hilar adenopathy. The edema of the left breast and arm persisted. Three weeks later, however, a recurrence of the pleural fluid and mediastinal adenopathy was noted and the patient was referred for nitrogen mustard therapy.

**Physical Examination.** The patient had a marked radiodermatitis of the left supraclavicular area. There were induration and edema of the left breast and upper extremity, a left Horner's syndrome as well as signs of pleural thickening over the left upper chest. There were no palpable glands, liver and spleen were not enlarged. Neurologic examination was negative.

**Laboratory Data.** Blood counts: leukocytes 7600, erythrocytes 3,540,000, hemoglobin 11.3 Gm, platelets 1,176,630, reticulocytes 1.3 per cent, differential: polymorphonuclear neutrophils 81 per cent, monocytes 7 per cent, lymphocytes 12 per cent. The urine was negative. The Hinton test was negative. Roentgenogram of chest showed enlarged hilar masses.

**Course.** On July 5, 1946 the patient was started on a course of 4 doses of HN<sub>2</sub> consisting of 4, 5, 6 and 7 mg. Chills and severe nausea followed each dose.

There followed a moderate regression of the edema of the left arm and breast and complete resolution of both hilar masses. In October 1946 the patient developed a spastic paraplegia and fecal and urinary incontinence. Combined roentgen therapy (1025 r to the lower cervical and upper thoracic spine) and HN<sub>2</sub> (24 mg) were administered. Severe nausea and vomiting followed each injection of the latter. During the course of the next three months incontinence completely disappeared and the patient could walk with assistance. Horner's syndrome persisted.

In February 1947, the patient again developed a spastic paraplegia. Lumbar puncture demonstrated the presence of a partial dynamic block and a spinal fluid protein of 120 mgs per cent. A third course of HN<sub>2</sub> was administered on four successive days (5, 6, 7 and 8 mg). Spinal fluid dynamics returned to normal and protein level fell to 60 mgs per cent. Roentgen therapy to the lower cervical and upper thoracic spine (725 r) produced no further effect upon the spinal fluid. There followed a gradual improvement in the use of both lower extremities.

In May 1947 the patient developed subcutaneous nodules over the left upper chest. These soon ulcerated and became secondarily infected. Progressive paralysis of the lower extremities resulted in a complete spastic paraplegia and urinary incontinence. The edema of the left arm became especially painful. All forms of therapy were refused. In September 1947 a large sacral ulcer developed and became secondarily infected. The patient ran a fever which did not respond to penicillin therapy. She was continuously sedated with large doses of morphine and pantopon. Death occurred on September 27, 1947. Postmortem examination was not obtained.

#### CASE 24

J. F. K., a 27 year old white male first noted the presence of left cervical adenopathy in December 1943. A biopsy revealed the presence of Hodgkin's granuloma. In November 1945 mediastinal involvement was noted. In March 1946 left inguinal glands appeared. Cervical glands recurred in July 1946. Roentgen therapy induced complete regression of enlarged glands. Complaints of anorexia, weakness, nausea, vomiting, epigastric and flank pain were relieved by roentgen therapy to the abdomen and back. In October 1946 the patient complained of left upper quadrant pain and paresthesias of the lower extremities. The upper abdominal pain subsided with x-ray therapy. Complete paraplegia and urinary incontinence developed in January 1947.

*Physical Examination.* The patient appeared chronically ill. He had enlarged cervical, left axillary, inguinal and femoral nodes. A lime-sized mass was palpable in the lower abdomen. The spleen was two fingers breadth below the left costal margin. There was a large sacral ulcer. Neurologic examination revealed a spastic paraplegia and hypesthesia from the level of D12. The patient had both urinary and fecal incontinence.

*Laboratory Data.* Leukocytes 18,900; erythrocytes 3,280,000; hemoglobin 72 per cent; differential polymorphonuclear neutrophils 89 per cent; monocytes 1 per cent; lymphocytes 10 per cent. The urine showed a trace of albumin and numerous white cells. The Mazzini test was negative.

*Course.* Two courses of HN<sub>2</sub> were administered, one beginning January 2, 1947 (22 mg.) and the other February 17, 1947 (22 mg.). This was followed by roentgen therapy (3200 r) over the lower dorsal and upper lumbar spine. The neurologic status however remained unchanged. Cervical and inguinal glands appeared about one month later. In June 1947 the patient developed edema of the left leg and scrotum which was unrelieved by mercurhydrin. Bladder incontinence required constant tidal drainage. In August 1947 enlarged cervical glands appeared and the patient had considerable dysphagia. He received 4 mg. HN<sub>2</sub> on August 18. The following day at the start of the saline infusion for the administration of nitrogen mustard he became dyspneic and cyanotic and complained of sudden blindness. His face became puffy and neck veins distended. Oxygen and morphine were administered with gradual improvement. A friction rub was heard at the left base twenty-four hours later. One month later a cutaneous ulcer developed at the base of the penis due to pressure from the paraplegic position. The patient died on October 17, 1947.

At autopsy there was granulomatous infiltration of cervical, axillary, inguinal, retroperitoneal, celiac, pancreatic and mesenteric lymph nodes, the spleen and liver as well as infiltration into the psoas muscle, kidneys, adrenals, bladder, pancreas and left lung. There were bilateral pyonephroses and pyoureteritis. A purulent cystitis was present. The lower thoracic portion of the spinal cord was surrounded by an epidural cuff of firm gray tumor 3 cm. in thickness. The left half of the cord was greatly compressed. The tumor extended through the dura and pia arachnoid directly into the substance of the cord. There was degeneration of the posterior and lateral tracts of the spinal cord. The vertebral marrow was entirely replaced by necrotic tissue. There was active hematopoiesis in the costal, sternal and calvarial marrow.

Therapy was instituted three weeks and three and one-half months after the initial symptomatology in cases 8 and 24 respectively. In the latter case, irreversible cord changes were undoubtedly present at the time of treatment. The former had a partial remission following combined therapy. The shorter interval between onset of symptoms and therapy is probably responsible for the difference in the results.

obtained. Secondary myelomalacia of the cord due to pressure and thrombosis of vessels is an irreversible process.

**Pain.** Pain was a prominent presenting symptom in three patients who showed evidence of intraspinal involvement of Hodgkin's disease.

*In case 25* the initial manifestation of the disease was in the form of agonizing low back pain radiating down the right leg. Roentgenogram of the spine revealed the presence of a destructive lesion in the twelfth dorsal vertebrae. A laminectomy performed one year later revealed an infiltrative mass involving the seventh, eighth, ninth and tenth dorsal spinous processes, laminae and pedicles as well as an extradural mass. Roentgen therapy did not relieve the pain. Because of the excruciating character of the pain the patient required large doses of morphine and demerol to which he became addicted. The patient subsequently had two convulsive seizures with shooting pains down both arms. Four courses of HN<sub>2</sub> were administered following which he developed complete remissions from the agonizing pain for the periods of 31, 43, 28 and 21 days respectively. The second course was combined with roentgen therapy. Further HN<sub>2</sub> had to be discontinued because of hematemesis. The patient died suffering extreme back pain radiating down both legs. At autopsy the extradural space from the lumbar to the upper cervical area was filled with tumor.

*Case 38* was completely relieved of pain following the first and partially relieved following the second course of nitrogen mustard.

The following case, showing remarkable pain relief following HN<sub>2</sub> therapy, is described in detail.

#### CASE 10 (FIGURE 10)

*B. D.* a 38 year old white male was first seen in October 1946. He had discovered a mass in the left axilla two and one half years previously and the diagnosis of Hodgkin's disease had been made following biopsy. Roentgen therapy was then administered to the left axilla, left supraclavicular region and mediastinum. In September 1944 the patient developed fever, night sweats and right axillary adenopathy. A submental gland appeared in December 1944.

Roentgen therapy was administered on these and subsequent occasions with progressively increasing radioresistance. The patient developed marked fatigue, lassitude, night sweats and anorexia.

**Physical Examination** (October 22, 1946) The patient was moderately pale. A large mass was present in the eleventh left intercostal space. There was no cervical axillary, or inguinal adenopathy. The liver was felt three fingers breadth below the right and the spleen five fingers breadth below the left costal margin.

**Laboratory Data.** Blood counts: leukocytes 15,650; erythrocytes 3,390,000; differential polymorphonuclear neutrophils, 44 per cent, band forms 10 per cent, lymphocytes 34 per cent, monocytes 10 per cent.

**Course.** The patient received four doses of HN<sub>2</sub> consisting of 4, 4, 5 and 6 mg. administered on alternate days. Moderate nausea and vomiting followed each injection and lasted for three to five hours. Within a few days the patient had a marked increase in vitality, an increased appetite and began to gain weight. The mass in the eleventh intercostal space and the hepatosplenomegaly regressed completely. The leukocyte level dropped to 3,950. This remission lasted for two and one half months. At that time the patient noted the presence of enlarged preauricular glands. On examination he was found to have generalized adenopathy, recurrent eleventh left intercostal mass and hepatosplenomegaly. A second course of HN<sub>2</sub> was instituted on December 26, 1946 in the form of weekly and biweekly injections. The nausea and vomiting were of such severity that further attempts at prophylactic therapy had to be discontinued. Adenopathy and hepatosplenomegaly regressed completely.

In February 1947 the patient noted the onset of headache and irritability. This was soon followed by intermittent pain in the right quadriceps muscle, severe sweats and anorexia. About one month later the patient complained of low back pain radiating down the right extremity, aggravated by coughing, sneezing and straining at stool. Neurologic examination was essentially negative. The pain shifted to the left lumbar area and radiated to the left hip and left thigh anteriorly. Roentgen therapy (300 r) to

the lumbar spine had no effect. The pain localized at L<sub>3</sub> and became progressively more intense. A lumbar puncture revealed a complete dynamic block, xanthochromic fluid and 872 mg per cent spinal fluid protein. Other physical findings and hematologic data are depicted in figure 10.

Beginning April 25, 1947 the patient received daily injections of 4, 5, 6 and 7 mg HN<sub>2</sub>. Moderate nausea and vomiting followed each dose. Within twelve hours after the first dose 90 per cent of the pain had subsided and moderate reduction in preauricular adenopathy was noted. The pain was almost completely relieved at the conclusion of therapy. A repeat lumbar puncture was performed on the following day and revealed normal dynamics, clear fluids and 39 mg per cent spinal fluid protein. Sweats and hepatosplenomegaly subsided completely. The usual fall in the leukocyte level occurred.

In July 1947 the patient noted a recurrence of weakness, anorexia and dizziness. On examination he was found to have marked pallor and hepatosplenomegaly. Blood counts were as follows: leukocytes

FIG. 10—EFFECTS OF HN<sub>2</sub> IN PATIENT WHO DEVELOPED AGONIZING LOW BACK PAIN AND EXTRADURAL INVOLVEMENT WITH HODOKIN'S DISEASE (CASE 10)

6000, erythrocytes 2,010,000, hemoglobin 6.9 Gm, reticulocytes 6.6 per cent, platelets 303,000 differential, normal. The blood sedimentation rate was 68 mm per hour. The urine urobilinogen was positive 10 x 320 dilution. The fourth course of HN<sub>2</sub> was started on August 9, 1947 and consisted of daily doses of 5, 6, 7 and 8 mg. The usual reactions of nausea and vomiting followed each dose. 1000 cc of whole blood were given to correct the anemia. There followed a marked improvement in anorexia and sweats. The hepatosplenomegaly subsided completely. The leukocyte level fell to 2900.

The remission lasted until October 20, 1947 when the patient again noted the onset of fatigability and anorexia. On examination he was found to have moderate pallor, preauricular and submental adenopathy and hepatosplenomegaly. The erythrocyte count had fallen from 4,040,000 to 3,300,000 with corresponding hemoglobin levels of 11.3 and 9.3 Gm, respectively. A fifth course of HN<sub>2</sub> was started on October 23, 1947 consisting of 5, 6, 7 and 8 mg administered on alternate days. The patient had a prompt improvement in general well being as well as complete regression of adenopathy and hepatosplenomegaly. The leukocyte level dropped to 3600. The platelet count rose to 404,500.

Following each of the five successive courses of HN<sub>2</sub> this patient demonstrated an unusual sensitivity to nitrogen mustard therapy with objective signs of improvement occurring as early as 12 hours after the initial dose. The response of pain and the regression of the intraspinal tumor were indeed remarkable. The consistent fall in erythrocyte and hemoglobin levels and reticulocytosis were quickly corrected with HN<sub>2</sub> therapy.

In this group presenting pain as the predominant symptom the results were far more striking than in those cases showing paraplegia, probably because pain is an early sign of intraspinal involvement and may therefore cause the patient to seek help before irreparable spinal cord damage has taken place. Thus pain was completely relieved in 71.4 per cent and partially relieved in 28.6 per cent of the cases.

### *Peripheral*

*Paralysis of the Upper Extremity* In 2 cases, paralysis of the upper extremity, secondary to pressure upon the brachial plexus was present. In neither case was nitrogen mustard effective in relieving the paralysis. Case 1, had a large mass filling the entire left side of the neck. Case 8 had extensive scar tissue in the supraclavicular region which resulted from previous intensive roentgen therapy. The cervical mass in former case showed partial regression but sudden death occurred before any improvement in the paralysis could be noted.

*Pain* Back pain in the absence of specific intraspinal disease was present in 7 patients. Complete subsidence of pain in all cases followed nitrogen mustard therapy. It is probable that dorsal root compression by granulomatous tissue was quickly relieved before irreversible changes had occurred.

*Horner's Syndrome* Seven patients having eleven administrations of HN<sub>2</sub> had Horner's syndrome. No change followed therapy in nine of eleven administrations.

### *Osseous Involvement*

Roentgenograms of the skeletal system revealed lesions in 6 patients. Vertebral lesions were present in 4 cases, pelvic and vertebral lesions in 1 case, and pelvic lesions alone in 1 case. A destructive lesion of the sternum was present in 1 case. Despite successful clinical remissions following nitrogen mustard therapy the destructive lesions as visualized roentgenologically showed no improvement. This lack of response may be due to the inhibitory effect of the nitrogen mustards upon osteoblastic and other enzymatic activities necessary for osseous regenerations.

## EFFECTS ON HEMATOLOGIC CONSTITUENTS

### *Peripheral Blood*

*Erythrocytes* Figure 11 illustrates the hematologic changes which followed HN<sub>2</sub> therapy. Fifty-eight and five-tenths per cent of cases showed a well defined decrease in the erythrocyte level. This was manifest within five to six days after the initiation of treatment, and persisted until the twenty-first to twenty-fifth day, after which a gradual increase to normal levels occurred. The maximum reduction in the erythrocyte count was 16.2 per cent. In 18.8 per cent of cases, erythrocytes rose

following therapy. The average rise was 12.2 per cent on the ninth to tenth day and 23.3 per cent on the twenty-sixth to thirtieth day. Twenty-two and seven-tenths per cent of cases showed slight if any change in red cell count. The routine examination of all peripheral blood films failed to reveal any striking morphologic changes in the red blood cells.

It is possible that the effect on red cell count may be due to a direct action of the chemical upon the circulating red cell. Boursnell, et al.<sup>30</sup> have demonstrated

FIG. 11.—REDUCTION IN THE VARIOUS HEMATOLOGIC CONSTITUENTS FOLLOWING A COURSE OF  $\text{HN}_2$  THERAPY. The platelet reduction as pictured above occurred in only 20 per cent of the cases. The most constant effect was on the leucocytes, more particularly on the granulocytic elements.

in rabbits, that one-third of the injected radioactive sulfur mustard remains affixed to the red cells. Increased urobilinogen excretion into the feces has been reported by Jacobson<sup>8</sup> and Urteaga<sup>30</sup> following the administration of nitrogen mustard. Serial serum bilirubin studies, performed in many of our cases, revealed no change. No spherocytosis or altered osmotic fragility of the red cells could be demonstrated.

Case 10, with each relapse, showed a marked fall in erythrocyte and hemoglobin levels and developed a spherocytosis and reticulocytosis. Following each course of nitrogen mustard therapy the erythrocyte and hemoglobin levels rose and spherocytes and reticulocytes diminished.

**Hemoglobin** A parallel fall in the hemoglobin level to that noted above occurred in 59.0 per cent of cases. A 7.1 per cent reduction was present on the fifth day, and a 12.1 per cent reduction on the fifteenth to twentieth day. Gradual improvement followed. In 41.0 per cent of cases, a rise in the hemoglobin levels to a maximum of 19.3 per cent on the twenty-first to twenty-fifth days was noted.

**Reticulocytes** Eighty-five and one-tenth per cent of cases showed a depression in the reticulocyte level following nitrogen mustard therapy. This was maximal on the sixth to tenth day (0.0 to 0.2 per cent).

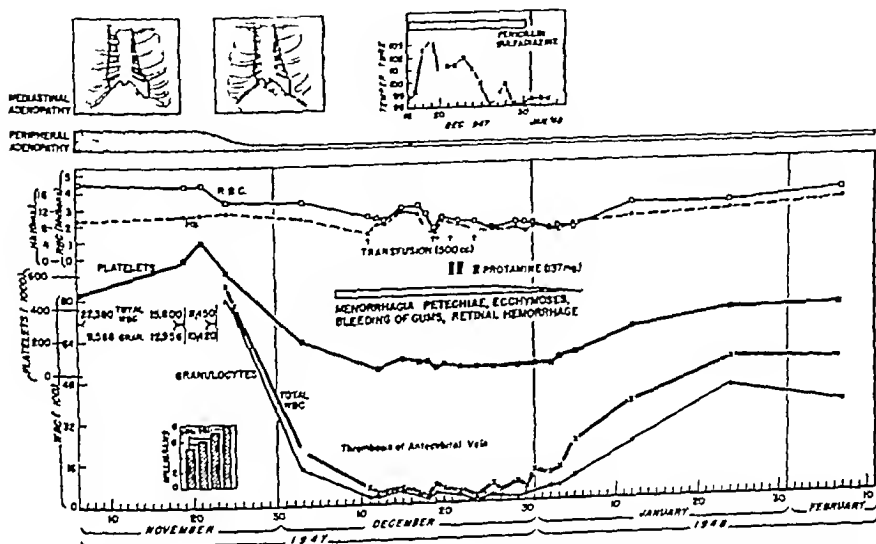

FIG. 12.—SEVERE HEMATOLOGIC COMPLICATIONS FOLLOWING ADMINISTRATION OF 18 MG  $\text{HN}_2$  AND 8 MG  $\text{HN}_2$  (CASE 49). The various features of aplasia of the marrow developed with severe anemia, granulocytopenia and thrombocytopenia. Hemorrhagic manifestations were severe. Patient recovered after a very stormy course and had an excellent remission.

**Leukocytes** A fall in the leukocyte level occurred in 87.7 per cent of cases. Those patients with initial leukocyte counts ranging from 4000 to 15,000 tended to develop leukopenic levels, while those ranging between 15,000 and 27,250 tended to fall to normal levels. The maximal fall in the leukocyte count occurred on the twenty-first to the twenty-fifth day after the initiation of treatment and was followed by a gradual return to normal levels on the thirty-sixth to fortieth day.

Five cases (6.9 per cent) with initial leukopenias after a slight decrease in the leukocyte count showed a progressive increase beginning on the sixteenth to twentieth day. Case 23 had an initial leukocyte count of 2600 which fell to 900 on the eleventh day and subsequently rose to 6920 on the thirty-third post-therapy day.

Case 49 showed the most marked leukocyte depression falling from 22,350 to 600 and lasting for forty days (fig. 12). This was associated with a corresponding reduction in the erythrocytes and platelets and progressive bone marrow hypo-

plasia. The etiologic role of tris-mustard in the production of this reaction is discussed below.

The decrease in the leukocyte count was predominately a reflection of the simultaneous decrease in granulocytes (figs 5, 9, 10, 12). Lymphocytes and monocytes showed moderate reductions only when their initial levels were high. Repeated examinations of the blood films revealed no qualitative changes in any of the white cell elements.

*Platelets* The platelet level was affected in only 20.5 per cent of the cases. In these cases, an average reduction of 69.4 per cent was present on the twentieth to thirtieth day following which a gradual increase occurred. Two patients with initially low platelet counts after a slight depression showed increases of 43.8 and 54.4 per cent.

### *Hemorrhagic Manifestations*

Upon the usual therapeutic schedule, 3 patients developed hemorrhagic manifestations following one or more courses of  $\text{HN}_2$ . Case 20, who had received a total of eight courses, developed moderate bleeding of the gums following her last course. Severe hematemesis followed the third and fourth doses of the fourth course in Case 28 and well as the fifth dose of the fifth course. Hematemesis occurred terminally eleven days after the first course in Case 22. The most severe hemorrhagic complications due to marked thrombocytopenia, occurred in Case 49 who received 18 mg of the tris compound ( $\text{HN}_3$ ) and 8 mg of  $\text{HN}$ . Her case is described in detail.

### CASE 49 (FIGURE 12)

*M. S.* a 19 year old white female first noted the presence of a right supraclavicular mass in October 1947. Within two weeks she began having severe night sweats and fever. Other glands appeared in the left cervical and axillary regions. The biopsy showed features of both Hodgkin's granuloma and sarcoma. The patient was first seen about one month after onset at which time she complained of cough.

*Physical Examination* The patient was moderately pale. There was a large left axillary mass 6 cm in diameter. There were numerous bean-sized axillary and cervical glands. Supracardiac dullness was increased. The liver and spleen were not palpable.

*Laboratory Data* Blood counts: leukocytes 15,180 erythrocytes 4,310,000 hemoglobin 10.4 Gm reticulocytes 0.5 per cent platelets 689,600 differential polymorphonuclear neutrophils, 82 per cent eosinophiles 3 per cent monocytes 4 per cent lymphocytes 11 per cent. Bone Marrow hyperplastic differential band forms 36 per cent metamyelocytes 22.5 per cent, myelocytes 11.6 per cent plasma cells, 1.2 per cent megakaryocytes markedly increased normoblasts A 0.8 per cent B 2.8 per cent, C, 4.0 per cent. The urine was negative. The Hinton test was negative. The blood sedimentation rate was 95 mm per hour. The total blood proteins were 7.1 Gm per cent albumin 4.4 Gm per cent, globulin 2.7 per cent. A roentgenogram of the chest showed large mediastinal and hilar masses.

*Course* The patient received three doses of  $\text{HN}_2$  (5, 6 and 7 mg respectively) and one dose of  $\text{HN}$  (8 mg) on alternate days beginning November 18, 1947. There was a strikingly rapid regression of cervical and axillary glands. On the fifth day following the initiation of therapy the mediastinal masses regressed 60 to 70 per cent. The patient's hematologic course is shown in figure 12. A marked pancytopenia with extreme thrombocytopenia developed. Severe menorrhagia, petechiae, ecchymoses, bleeding of gums and a retinal hemorrhage occurred eighteen days after the initiation of therapy. Thromboses of the right and left antecubital veins were present. Serial bone marrow aspirations revealed progressive hypoplasia (fig 13). The patient ran a febrile course for ten days. During this time she received penicillin and sulfadiazine. A total of 3500 cc of fresh whole blood was administered. Protamine 137 mgs was

administered intravenously but without apparent effect upon the hemorrhagic manifestations. These subsided spontaneously with an improvement in the platelet count. Definite evidence of bone marrow regeneration was noted on January 5, 1948.

The  $\text{HN}_2$  administered to this patient was undoubtedly largely responsible for the severity of the hemorrhagic complications. This form of nitrogen mustard was found to produce unusually severe depressions of leukocyte, erythrocyte and platelet levels. Thromboses of injected veins were likewise more common. Further use of tris-mustard appears to be unwarranted.

### *Bone Marrow*

Serial bone marrow studies were performed in 11 cases of Hodgkin's disease treated with nitrogen mustard. Within twenty-four hours after the initiation of nitrogen mustard therapy the clumps of marrow began to show a decrease in size and cellularity. Fat-spaces were increased.

Polymorphonuclear neutrophils showed hypersegmentation. Erythropoiesis was suppressed. Within two to four days there was a reduction in the number of myelocytic cells and a relative increase in the number of more mature forms. Bizarre, distorted myelocytes, metamyelocytes, polymorphonuclear neutrophils and megakaryocytes were noted with moderate frequency. Marked hypoplasia of the bone marrow followed nitrogen mustard therapy in 7 cases. The serial bone-marrow changes obtained in 1 case are shown in fig. 13. Case 46 showed a marked decrease in cellularity within 24 hours after the initiation of therapy. Increasing hypoplasia was found two days later. Bone marrow regeneration was noted six days after the cessation of therapy. The pretherapy bone-marrow of case 35 was markedly hyperplastic. Severe hypoplasia was present nine days after the initiation of treatment.

A moderately active bone-marrow was present in Case 16 who died fifteen days after the completion of the last course of nitrogen mustard. Hyperactive marrows were found at autopsy in 2 cases (Cases 15 and 24) who died five and ten months, respectively, after their last course of therapy.

Suppression of erythroid activity was noted within twenty-four hours after the initiation of  $\text{HN}_2$  therapy. No immediate reflection of this depression was noted in the peripheral erythrocyte and hemoglobin levels, in all probability because of the normal red cell survival time of one hundred and twenty days.

Bloom and Bloom<sup>40</sup> showed that the chick erythroblast was the most sensitive cell in the marrow following the administration of x-ray therapy.

Suppression of granulopoiesis was noted within two to four days. The fall in the peripheral leukocyte level occurred shortly thereafter reaching a maximal leukopenia on the twenty-fifth day. This prompt reflection of an effect on the marrow is undoubtedly due to the short survival time of the leukocyte in the peripheral blood.

Megakaryocytes proved to be the most resistant of all marrow elements and platelet reduction occurred in only 20.2 per cent of cases.

Except for terminal cases dying shortly after their course of nitrogen mustard therapy no cases of irreversible aplasia of the marrow were encountered in this

FIG 13 —HYPOPLASTIC RESPONSE OF BONE MARROW FOLLOWING INJECTION OF 18 MG TRIS (B CHLOROETHYL) AMINE AND 8 MG METHYL BIS (B CHLOROETHYL) AMINE (CASE 49)  
(a) PRIOR TO INITIATION OF THERAPY

FIG 13 —(b) EIGHT DAYS AFTER INITIATION OF THERAPY

FIG 13 —(c) TWENTY DAYS AFTER INITIATION OF THERAPY

FIG 13 —(d) THIRTY EIGHT DAYS AFTER INITIATION OF THERAPY

series. However, we have been informed of such instances from other clinics where a higher dosage schedule of  $\text{HN}_2$  and more frequent institution of therapy have been in vogue. Our experience indicates that the tris compound has a much greater cytotoxic effect upon the bone marrow than does the methyl Bis (B chloroethyl) amine.

In experimental animals, the rapidity of the cytotoxic action of the nitrogen mustard has been demonstrated by Karnofsky et al.<sup>29</sup> This occurs within a period of five minutes after injection. The fixation of radioactive sulfur mustard to the bone marrow was shown by Boursnell et al.<sup>30</sup> Kindred<sup>41</sup> studied the reaction of the femoral bone marrow of the albino rat to sulfur and three nitrogen mustard preparations. A marked suppression of erythroid and granulocytic elements was noted two days after injection. Mitotic activity was diminished. Megakaryocytes showed some signs of injury but no reduction in number. Reticulum cells and plasma cells were unaffected. Similar results were obtained in dogs, rabbits,<sup>42</sup> and in mice.<sup>37</sup>

Severe aplasia of the bone marrow following mustard gas poisoning was reported in 6 fatal cases by Krumbhaar and Krumbhaar<sup>6</sup> in 1919. Spurr, et al. using the marrow aspiration technique<sup>32</sup> found a more prolonged depression of the marrow and a less rapid return to normal than noted in our cases. Block et al.<sup>43</sup> studied the serial marrow changes histopathologically. The atrophic stage was between eight and twenty days after initiation of  $\text{HN}_2$  therapy. In the post-mortem findings reported by Spitz,<sup>44</sup> severe marrow hypoplasia was noted following a cumulative dose of 0.5 to 0.6 mg./kilo of  $\text{HN}_2$  administered eight days prior to death.

Barron et al.<sup>45</sup> showed that the addition of choline, dimethyl amino ethanol and methionine to bone marrow in vitro protected it from the inhibition of respiration by the nitrogen mustards.

### *Lymph Nodes*

Serial lymph node aspiration were performed in six treated cases. The typical appearance of the lymph node aspiration in Hodgkin's disease is shown in fig. 14a. This is characterized by a pleomorphic cellular pattern consisting of lymphocytes, polymorphonuclear neutrophils, eosinophils, plasma cells, reticulum cells, and Dorothy Reed cells. Within a period of twenty-four hours after the initiation of therapy there was a decrease in cellularity and pyknosis and smudging of lymphocytic cells. Four days after the initiation of therapy, these findings were more marked (fig. 14b). Polymorphonuclear neutrophils showed vacuolation and hypersegmentation. Reticulum cells were bizarre and degenerate and showed frequent vacuolation.

No change was noted in the lymph node aspirations of a case of Hodgkin's sarcoma (Case 46) who was resistant to treatment. Case 49, having some features of both Hodgkin's granuloma and sarcoma showed a marked reduction in the pleomorphism present before therapy with large numbers of sarcoma cells still present after therapy. The lymph nodes of Case 30, who died from an exanguinating gastrointestinal hemorrhage twenty-four hours after receiving 4 mg. of  $\text{HN}_2$ , showed marked pyknosis and diminished mitotic activity. Figure 15 shows a multi-

FIG. 14—EFFECTS OF NITROGEN MUSTARD ON LYMPH NODE OF CASE OF HODOKIN'S DISEASE (CASE 17)  
(a) PRIOR TO INITIATION OF THERAPY

FIG. 14—(b) SAME PATIENT FOUR DAYS AFTER INITIATION OF THERAPY

ary focus of necrosis within a lymph node obtained at postmortem examination seven days after the institution of nitrogen mustard therapy (Case 28)

Similar results were noted by Block et al.<sup>43</sup> and Spitz.<sup>44</sup> Focal necrosis of the splenic pulp was reported by the latter following cumulative doses of 0.5 to 0.8 mg./kilo, administered seven to eight days before death. Kindred<sup>45</sup> showed marked lymphoid atrophy and lymphocytic degeneration in the albino rat on the second postinjection day. Similar changes were present in the thymus and the spleen. The peripheral lymphocytopenia coincided with decreased production within

FIG. 15.—LYMPH NODE OBTAINED AT POST MORTEM EXAMINATION SEVEN DAYS AFTER INITIATION OF NITROGEN MUSTARD THERAPY SHOWING A FOCUS OF MILIARY NECROSIS (CASE 41)

lymphoid organs rather than a direct effect upon the peripheral lymphocyte. Mice and rabbits showed essentially the same changes.<sup>27</sup>

#### *Liver*

Case 30 who died one day after a single injection of 4 mg. HN<sub>2</sub> showed an increase in the number of polymorphonuclear cells within the sinusoids. Milium foci of necrosis of the liver were noted at postmortem examination in 3 cases (Cases 16, 28 and 35), who died nine, ten and nineteen days, respectively, after the initiation of therapy. The liver cells showed extensive necrosis with very little leukocytic reaction (fig. 16). Four cases who died from fifty-four days to eight months after their last course of treatment showed no evidence of such milium foci of necrosis.

Nitrogen mustard appears to exert a karyolytic effect upon liver cells. Polymor-

phonuclear infiltration is present within twenty-four hours. Resolution of the necrotic foci probably takes place between nineteen and fifty-four days after the institution of therapy. Bournsnel, et al.<sup>20</sup> demonstrated the ability of the rabbit liver to concentrate as much as 50 per cent of the injected radioactive sulfur mustard within the bile within one hour. It is probable during this time that the hepatotoxic effect occurs. Zimmerman<sup>18</sup> reported focal necroses in the liver of cats after the oral administration of nitrogen mustard.

FIG. 16.—MILIARY FOCUS OF LIVER NECROSIS IN CASE OF HODGKIN'S DISEASE WHO DIED NINETEEN DAYS AFTER LAST COURSE OF NITROGEN MUSTARD THERAPY (CASE 16)

#### COMMENT

We prefer to classify Hodgkin's disease as a malignant proliferation of reticulum cells originating in lymphoid tissue, perhaps as a result of various stimuli including infections. The Sternberg-Reed giant cell, the type cell of this proliferative process, may represent a malignant type of reticulum cell. As with all neoplastic processes, Hodgkin's disease varies greatly in growth potentiality from case to case. In the most benign types giant cells are scarce and a tendency to fibrosis is marked. In the most highly malignant (Hodgkin's sarcoma), giant cells are

common and but little tendency to fibrosis is present. Dissemination of the disease ordinarily occurs by way of the lymphatic channels and by contiguity, and only rarely by way of the blood stream. Whatever the growth potentiality of the disease may be in a given case its course is relentlessly progressive. From peripheral lymph nodes, it extends to the mediastinum and the spleen. Thence, it spreads to visceral organs and constitutional symptoms of fever, night sweats, increasing weakness and itching appear. Terminally, it may block large lymphatic channels and cause huge tumor masses in various parts of the body.

The course of Hodgkin's disease may be terminated by complete extirpation of a single node or a small group of nodes if this is the only source of the disease. Such a successful end result is extraordinarily rare since once the diagnosis has been made, the disease has already spread. X-ray therapy has been used for many years to shrink the tumor masses and produce remissions. We have been impressed with the better results obtained in early cases by *drastic* x-ray therapy as opposed to the use of just enough x-ray to induce a reduction in lymph node size to normal. Sooner or later, despite x-ray therapy, new lymph node masses develop and constitutional symptoms become marked. At this point, x-ray therapy often has but little effect. The use of  $\text{HN}_2$  has to our mind revolutionized at least this phase in the treatment of the disease.

In the course of our studies it became apparent that  $\text{HN}_2$  is a valuable therapeutic tool in the treatment of Hodgkin's disease, in many cases, indeed, it presents distinct advantages over the more standard form of therapy by x-ray.  $\text{HN}_2$  has been particularly valuable in the terminal cases of Hodgkin's disease, i.e., in individuals completely disabled by their disease, having visceral involvement, and running an irregular or relapsing fever. The use of a single course of  $\text{HN}_2$  in such cases has often resulted in a termination of the febrile state and its associated symptom, the drenching night sweat. Frequently, there is a dramatic upsurge in vitality and a resumption of normal or almost normal activity. Severe itching of the skin, with its common accompaniments of excoriations and ulcerations due to scratching has usually yielded to  $\text{HN}_2$  when previous x-ray therapy has proved completely ineffective.

In those cases that have become refractory to x-ray therapy, whether the Hodgkin's process is generalized or of a more or less localized character, the use of  $\text{HN}_2$  may be invaluable. A single therapeutic course of  $\text{HN}_2$  often results in a very rapid and striking response with a marked simultaneous reduction in large lymphoid masses and spleen and in amelioration of both local and constitutional symptoms. The pain of peripheral nerve or spinal cord involvement has yielded quickly in all our cases to  $\text{HN}_2$  therapy even though previous x-ray therapy has been completely ineffective. A frequent finding is the enhancement of sensitivity to x-ray therapy following a course of  $\text{HN}_2$ .

Thus,  $\text{HN}_2$  has proved invaluable in salvaging some of the apparently hopeless cases of Hodgkin's disease and in increasing their life span by periods ranging from two months to more than two years. Although the results in terminal cases have at times seemed almost *miraculous*, they have nevertheless been of temporary nature. Treatment with  $\text{HN}_2$  should in no sense be considered as curative.

The new sense of well being obtained with  $\text{HN}_2$  has however proved of great psychologic value and has often given the patient a renewed determination to cope with his illness.

Our experience with the treatment by  $\text{HN}_2$  of early or only slightly advanced cases has been too limited to warrant any definite therapeutic evaluation. In such cases, in which only a single group of nodes is apparently involved, the distinct possibility is present that some of the abnormal cells of the disease have already progressed beyond the local lesion. Although a sufficiently high dosage of x-ray therapy is usually productive of a sustained remission, the use of  $\text{HN}_2$  under these circumstances may help to destroy abnormal cells at a distance from the local process. Particularly in the early cases of Hodgkin's disease, drastic therapy by all available means is important. This may include radical extirpation of a mass of glands, heavy dosage of high voltage x-ray, and  $\text{HN}_2$ .

There seem to be few contraindications to the use of  $\text{HN}_2$ . In the presence of leukopenia, the granulocytes should be carefully watched and treatment with penicillin given when a distinct granulocytopenia develops. When jaundice is present  $\text{HN}_2$  should be given with particular care since further injury to the liver may develop. If anemia is present, transfusions should be given either prior to the course of  $\text{HN}_2$  or during its administration.

We have had better results in our cases with the use of smaller rather than larger doses of  $\text{HN}_2$ . A complete remission is usually attended with the use of doses smaller than the customarily recommended amount of 0.1 mg per Kg of body weight. Reactions, particularly those of a hematologic nature, are usually slight. Larger doses of  $\text{HN}_2$  may be productive of extremely severe and indeed irreversible reactions.

Although x-ray therapy is still the method of choice in the early cases of Hodgkin's disease and is productive of longer remissions than is  $\text{HN}_2$ , the combined use of x-ray and  $\text{HN}_2$  may prove to be better than that of either therapeutic method given alone. We have obtained the impression that  $\text{HN}_2$  is more specific against reticulo-endothelial cellular proliferations than against those of any other cell type.  $\text{HN}_2$  must therefore be considered as a definite addition to our present therapeutic armamentarium of attack against Hodgkin's disease, which we consider to be a form of reticulum cell proliferation. It is realized that the use of  $\text{HN}_2$  leaves much to be desired, since it destroys abnormal cells leaving others which continue to maintain neoplastic potentialities. These ultimately proliferate, leading to relapse. However, it is hoped that further research will result in the development of even more potent chemotherapeutic agents for the ultimate control of the disease.

#### SUMMARY

1. Methyl bis (B chloroethyl) amine ( $\text{HN}_2$ ) was given by intravenous route for the treatment of 50 successive cases of Hodgkin's disease, most of them severe and far advanced. Doses somewhat smaller than the usually recommended amount of 0.1 mg per Kg were used in courses of four to six injections.

2. Nausea and vomiting followed administration of the drug in 93.2 per cent

of cases. Chills and fever occurred in 12.4 and 6.8 per cent of cases respectively. Dyspnea, cyanosis and diarrhea were rare.

3. In previously untreated cases, remissions were of much shorter duration than those obtained with Roentgen therapy. However, striking remissions were commonly obtained in x-ray resistant cases. Remissions lasted from 17 to 331 days and in individuals receiving multiple courses were roughly proportional to the total dosage administered. A moderate prolongation of the remission period was obtained when HN<sub>2</sub> was combined with roentgen therapy.

4. Constitutional symptoms such as fever, night sweats, weakness and itching responded exceedingly well in most cases to HN<sub>2</sub> therapy. Many previously incapacitated patients were completely rehabilitated for several weeks to several months after a single course of HN<sub>2</sub> therapy.

5. Adenopathy and splenomegaly regressed in 70.2 and 71.7 per cent of cases respectively. Lymphoid masses previously resistant to x-ray therapy appeared to develop increased sensitivity to x-rays after a course of HN<sub>2</sub> therapy.

6. Patients with extensive mediastinal involvement and obstructive symptoms responded only moderately well while those with lesser degrees of involvement showed a better response.

7. Paraplegia due to intraspinal involvement was partially relieved in half the cases while pain due to similar involvement was dramatically relieved in all cases. Pain due to pressure upon peripheral nerves was similarly relieved in all cases.

8. A slight but definite fall in the erythrocyte and hemoglobin levels occurred within five to six days after the institution of therapy. Reticulocytes were maximally depressed on the sixth to tenth days. Of the leukocytic elements, the granulocytes were predominately affected, with maximal cytopenic levels on the twenty-first to twenty-fifth day. The leukocytes gradually returned to normal by the thirty-sixth to fortieth day. Cases presenting an initial leukopenia tended to develop normal leukocyte counts after an initial drop to low levels. The platelet count was affected in only 20.5 per cent of cases. Terminal cases at times developed marked pancytopenia.

9. In one case severe hemorrhagic complications due chiefly to thrombocytopenia followed the administration of the tris form of nitrogen mustard and gradually subsided after a very stormy course.

10. Progressive but temporary marrow hypoplasia followed nitrogen mustard therapy in eleven cases studied with serial marrow punctures. Erythroblastic depression was noted within twenty-four hours and granulocytic depression within forty-eight to seventy-two hours. The megakaryocytes proved to be the most resistant of the marrow elements. The marrow picture usually returned to normal spontaneously within a period of six to eight weeks after the cessation of therapy.

11. Lymph node punctures revealed degeneration and pyknosis of lymphocytes within twenty-four hours after the institution of therapy with a subsequent gradual disappearance of polymorphonuclear neutrophils, eosinophiles, plasma cells, reticulum cells and Dorothy Reed cells. Military foci of necrosis were demonstrated in a gland obtained at post mortem seven days after the institution of HN<sub>2</sub> therapy.

12. Military foci of necrosis were demonstrated in the liver of 3 cases dying be-

tween nine and nineteen days after the institution of  $\text{HN}_2$  therapy. No such findings could be found in a case in which death occurred fifty-four days after the initiation of therapy.

13. The therapeutic results with  $\text{HN}_2$  in Hodgkin's disease appeared to have little relationship to the histologic appearance of the involved tissue. The immediate response in so called Hodgkin's sarcoma was particularly striking, and in one case, a remission lasting about a year took place.

### CONCLUSIONS

1. Nitrogen mustard ( $\text{HN}_2$ ) is a useful drug in the treatment of Hodgkin's disease, particularly in severe cases with marked constitutional symptoms and visceral involvement. In these cases, a period of complete rehabilitation and a definite increase in life span of from two months to two years may follow the use of one or several courses of  $\text{HN}_2$ .

2.  $\text{HN}_2$  appears to have an almost specific affinity for the abnormal tissues of Hodgkin's disease. Although a chemical without any radioactivity, its effects resemble closely those of x-ray. It is however often effective in producing complete remissions in cases that have proved completely refractory to continued x-ray therapy. A resumption in radiosensitivity may follow the use of a course of  $\text{HN}_2$  therapy.

3.  $\text{HN}_2$  offers certain advantages other than simplicity of administration over x-ray therapy. Its quick action by intravenous route often results in a simultaneous reduction of all affected lymphoid tissues. In involvement of the spinal cord or peripheral nerves,  $\text{HN}_2$  is far more effective, particularly in pain relief, than is x-ray.  $\text{HN}_2$  is likewise more effective in bringing about relief of fever and severe generalized itching than is x-ray. The one outstanding characteristic of the drug is its effectiveness in inducing complete or partial remissions in certain generalized or febrile cases that have been completely unaffected by persistent x-ray therapy. Repeated remissions may be induced by giving repeated courses of  $\text{HN}_2$ .

4. In relatively early cases of Hodgkin's disease, x-ray therapy is the treatment of choice, primarily because longer remissions can be obtained than with  $\text{HN}_2$ . However, it is possible that the best form of therapy, even in these cases, is that of the combined use of  $\text{HN}_2$  and x-ray, the  $\text{HN}_2$  being given for its effect upon proliferating cells which may either be at a distance from the local lesion or else so situated as to remain untouched by x-ray.

5. With cautious use of the drug, the reactions following  $\text{HN}_2$  therapy are rarely severe enough to militate against its use. Severe granulocytopenia can be handled prophylactically by the use of penicillin. Severe thrombocytopenia rarely occurs. The only definite contraindication to the use of  $\text{HN}_2$  is the presence of jaundice, indicating some degree of hepatic dysfunction.

6. Doses of  $\text{HN}_2$  somewhat smaller than the generally recommended one of 0.1 mg per kg of body weight are usually completely effective and are furthermore productive of minimal reactions.

7. As with all very quickly acting and potent drugs,  $\text{HN}_2$  must be used with

great care. Properly used, it has a well defined place in the treatment of Hodgkin's disease. Although cures are not to be expected and remissions are temporary, such remissions offer great comfort to the patient seriously ill with Hodgkin's disease. It is possible that  $\text{HN}_2$  may be the forerunner of other even more effective chemotherapeutic agents.

## PREPARATION OF STABILIZED SOLUTIONS OF HEMOGLOBIN

By ROBERT B PENNELL, PH D, AND WILLIAM ELLIOTT SMITH, B S

**D**URING the recent war the need for whole blood for its oxygen-carrying capacity and the supply of human red cells derived from the plasma program revived interest<sup>1-3</sup> in the long controversy as to the usefulness of hemoglobin solutions in therapy. That there should have been such a controversy was due in large part to the lack of availability for study of a standard hemoglobin solution of high stability prepared with adequate bacteriologic control, and to the consequent difficulty of interpreting much of the published work. This has been emphasized by Hamilton, et al.<sup>1</sup> We had the privilege of working with two of the groups which undertook the reinvestigation of this problem, that of Dr. William R. Amberson of the University of Maryland Medical School and that of Dr. Donald D. Van Slyke of the Hospital of the Rockefeller Institute, N. Y. From the work of each of these groups a standard hemoglobin solution suitable for clinical study was developed.<sup>1, 2, 4, 29</sup> Stability of these solutions could be maintained, however, only by special treatment, exhaustion of oxygen by high vacuum in the one instance and refrigeration in the other.

Hemoglobin in solution exists in three forms<sup>30</sup> which are in equilibrium, two of which, oxyhemoglobin and reduced hemoglobin, are physiologically active (i. e., they can act as oxygen carriers) and one of which, methemoglobin, is physiologically inactive. One of the physiologically active forms, reduced hemoglobin, is stable<sup>31-34</sup> and the other is not.<sup>1</sup> The instability of hemoglobin in solution is first manifested by its conversion to the physiologically inactive methemoglobin.

The three forms of hemoglobin also occur within the red cell, which is so constructed, however, that the hemoglobin within it is maintained in an active oxygen-carrying form, the inactive methemoglobin being kept at an extremely low level.<sup>35-37</sup> In the course of our studies we found methods of preparing solutions of hemoglobin by which the mechanism for maintenance of its oxygen-carrying capacity was preserved. This resulted in a hemoglobin solution which would convert itself to the stable reduced hemoglobin form,<sup>34</sup> thus obviating the special treatments usually necessary for storage of the solutions. The present study is concerned with delineation and demonstration of the factors of importance to the preparation of this type of solution.

### METHODS, TESTS AND EQUIPMENT

Total hemoglobin and methemoglobin contents of hemoglobin solutions were determined with the Evelyn photoelectric colorimeter employing the method of Evelyn and Malloy.<sup>38</sup> The values so obtained were found to check well with those obtained in other laboratories by other methods.<sup>39</sup>

The pH of solutions was determined by glass electrode without dilution of the hemoglobin solutions. Sodium and potassium concentrations of solutions were determined by the flame photometer.<sup>40</sup>

Tests for pyrogenic substances were carried out in accordance with the Minimum Requirements for Pyrogen Tests on Biologic Products from Blood Serum. Nov. 19, 1945. National Institute of Health.

From the Department of Immunoochemistry, Sharp and Dohme, Inc., Glenolden, Pennsylvania.

Sterility tests and animal safety tests were carried out in accordance with the Federal Register of September 16, 1947 as amended in January 1948. Since hemoglobin solutions form precipitates when added to the culture medium used in the sterility test, subcultures were made at the end of one week and the final test was read two weeks after the date of testing.

Pyrogen free water was prepared by double distillation, followed by immediate use, or by immediate storage at 2°C for not more than sixteen hours.

Total reducing substances and nonfermentable reducing substances were determined by the method of Benedict.<sup>48</sup>

Inorganic phosphorus was determined by the method of Embden and Fetter.<sup>49, 50</sup>

Lipid phosphorus was determined by the method outlined in *Quantitative Clinical Chemistry*, by Peters and Van Slyke, vol. II, page 884, 1st Edition, 1932.

## PREPARATION OF HEMOGLOBIN SOLUTIONS

*Source of Blood Cells* Sterile human red blood cell residues were obtained from commercial bleedings from the plasma processing unit of Sharp and Dohme. The bleedings were drawn in sodium citrate solution and approximately seventy-two hours elapsed between the time of bleeding and the time that the red cell residues were available for hemoglobin preparation.

*General Measures Observed* Rapidity of operation and maintenance of optimal working conditions were employed rather than aseptic handling during preparation of the solutions. Starting with sterile red cells, the entire operation was invariably completed and the final solutions sterilized within the course of eight hours. All work was performed at 2°C in a laboratory equipped with Sterilamps. All equipment coming in contact with the solutions was carefully cleaned and rinsed with pyrogen free water immediately before use. Pyrogen free water was used throughout for all dilutions and all solutions added to, or coming in contact with, the cells and hemoglobin. All hemoglobin solutions were submitted for sterility and for pyrogen and safety testing immediately after preparation.

*Washing and Laking of Red Blood Cells* From 2 to 5 liters of packed human red cells were washed by suspension in 2 volumes of 6 per cent dextrose solution containing 0.15 per cent nicotinic acid amide and 0.006 per cent ammonia, followed by centrifugation in a laboratory model Sharples Super Centrifuge using the Sharples blood separator bowl. With this bowl the wash solution is delivered from one outlet and the washed cells from another. The cells were ruptured during centrifugation and were caught in a container holding a small amount of nicotinic acid amide solution (containing sufficient nicotinic acid amide to provide 0.15 per cent in the estimated final volume of solution). The washed, ruptured cells were diluted with 2 volumes of dextrose solution (sufficient dextrose is used to provide 6 per cent in the estimated final volume of hemoglobin solution).

*Precipitation of Stroma*<sup>1</sup> The mixture was adjusted to pH 5.7-5.8 with 0.1 N hydrochloric acid at which pH the stroma was readily removed by centrifugation in a large Sharples Super Centrifuge using a clarifying bowl. The addition of the acid was accompanied by brisk mechanical stirring. The acid was allowed to run in a thin stream from a capillary pipette near the vortex of the stirring solution. Approximately 250 cc of 0.1 N hydrochloric acid per liter of solution may be added before determining the pH.

*Removal of Excess Potassium*<sup>1</sup> The centrifuged mixture was treated with sodium zeolite (decalso)\* to reduce the potassium content. Approximately 30 Gm of sodium zeolite per liter of solution was added and the mixture was stirred gently for ½ hour, after which the sodium zeolite was allowed to settle for ten to fifteen minutes. The solution was then decanted.

*Adjustments to the Final pH and Composition* Sufficient solid sodium bicarbonate was added to the solution to neutralize the hydrochloric acid added and to provide a slight excess.<sup>1</sup> It was found that 7.9 Gm of sodium bicarbonate per liter of solution provided a pH of 7.2 to 7.3 at this point. The final concentration of hemoglobin was adjusted to approximately 7 per cent, that of dextrose to 6 per cent and that of nicotinic acid amide to 0.15 per cent. To the solution was added, per liter, 5 cc of ammonium hydroxide solution (5 parts of Baker's A.C.S. ammonium hydroxide to 100 parts of water) to provide a concentration of 0.006 per cent  $\text{NH}_3$ , 4 cc of 1 per cent merthiolate (to provide a concentration of 1:25,000), 24 mg

\* Manufactured by the Permutit Co., New York, N. Y. Since earlier work had indicated the occasional presence of pyrogenic material in decalco it was always washed as described by Smith and Pennell in *J. Biol. Med.* 54, 715, 1947.

$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$  (1 cc of 2 per cent solution) 23 mg  $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$  (1.15 cc of 2 per cent solution) and 19.5 mg  $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$  (0.99 cc of 2 per cent solution) providing 0.1 millimolar concentration of each of the metals, and 20 mg of Nile blue (2 cc of 1 per cent solution). In a few of the later solutions 1 Gm per liter of the calcium salt of hexose diphosphate\* was added before stirring with decalzo. The  $\text{Ca}^{++}$  ions were removed from solution by the ion exchange agent.

**Sterilization by Sinter Filtration** The solution was filtered through K6 clarifying pads and sterilized by filtration through S4† pads using a Republic filter press. The clear red filtrate was caught in a sterile bottle containing a sterile syphon which could be used for filling the solution into a series of small containers. Samples taken at the time of filling these small containers were tested for pyrogenicity, sterility and safety. The solutions were held at 2 C until the completion of these tests.

### PROPERTIES OF HEMOGLOBIN SOLUTIONS

Solutions prepared according to the procedure just described were crystal clear and of deep red color. The hemoglobin of the solutions was more than 98 per cent active. Thorough examination indicated complete inability of the solutions to agglutinate A, B or O cells. Examination of the serum of patients before and two weeks after the injection of these solutions has shown no increase in the titer of anti-A and anti-B isohemagglutinins. Lipid phosphorus determinations showed that upon removal of the stroma less than 10 per cent of the lipid phosphorus remained in the solution, a figure corresponding closely to the 5-10% of lipid carbon reported by Hamilton, et al.<sup>1</sup> In a typical preparation the solution contained 5.56 milliequivalents of potassium, as compared to 19 milliequivalents before decalzo treatment. These solutions, when in sealed containers with little air space were completely converted to reduced hemoglobin in one to two days at 37 C, in two to three days at 25-27 C, or in seven to eight weeks at 2 C. During this conversion the presence of methemoglobin in quantities greater than 2-3 per cent of the total pigment was not detectable by daily examination. The reduced hemoglobin so obtained has been observed for twenty four months at 25-27 C without a change in the percentage of active hemoglobin. There may be, however, gradual deposition of a sediment during this time, the amount of sediment being a function of the speed of disappearance of oxygen, the amount of oxygen to be consumed, i.e., the amount of air space in the bottle, and the temperature of storage. No noticeable sediment has been encountered in solutions stored at 2 C. (Cursory examination of the sediment has shown it to be in part carbohydrate in nature, giving no reduction before hydrolysis and indicating a mixture of aldo- and keto-sugars after hydrolysis.) Shaking of the solutions, with consequent foam formation, may result in the appearance of films due to surface denatured protein. None of these phenomena has been found to have influence, detectable by the methods employed on the activity of the hemoglobin itself. These solutions lend themselves readily to lyophilization as will be described in a subsequent publication.

### EFFECTS OF VARIOUS STEPS ON THE CAPACITY OF THE SOLUTIONS TO FORM REDUCED HEMOGLOBIN

Neill<sup>24</sup> showed that since oxyhemoglobin and reduced hemoglobin have different colors, hemoglobin solutions in sealed containers could act as indicators of the

\* Schwartz Laboratory Inc., New York N. Y.

† Republic Filter Corp. Paterson N. J.

loss of oxygen from solution due to the action of enzyme systems which he added Warburg<sup>61</sup> had similarly made use of this phenomenon in following respiration of intact avian red cells Neill showed that when removal of oxygen from solution was rapid, the accumulation of methemoglobin did not occur It has since been shown by many workers<sup>42-50</sup> that methemoglobin itself may be reconverted to active hemoglobin by the action of enzyme systems Evelyn and Malloy<sup>65</sup> developed methods based on the light absorption of the cyan derivatives of these pigments which allow this interconversion to be followed quantitatively The aging data reported below were obtained by measurements of the accumulation and disappearance of methemoglobin by the method of Evelyn and Malloy in sterile hemoglobin solutions stored in sealed vials with a small amount of air space A separate vial was opened for each determination and was then discarded The aging test

TABLE 1—*Changes in Reducing Substances and Inorganic Phosphorus During Preparation of Hemoglobin Solutions*

	Total reducing substances	Nonfermentable reducing substances	Inorganic P
I	13.4	12.5	0.98
II	2.6	0.90	4.4
III	1.7	1.28	2.55
IV	1.7	0.81	3.05
V	1.5	0.48	2.62
VI	1.42	0.42	2.11

for a particular solution was considered to be completed when the accumulated methemoglobin had been reconverted to hemoglobin, or, when methemoglobin accumulation was not detected, upon the appearance of the typical grape-juice color of reduced hemoglobin

The data to be presented are strictly comparable only when obtained from a single pool of cells In table 1 it is evident that the amount of fermentable reducing substances in the cells obtained from the plasma laboratory was much less than in cells from a fresh bleeding, and at the same time, the inorganic phosphorus was elevated It is well known that after exhaustion of the available substrate, red cells cannot be restored to their original state of metabolism<sup>6</sup> The status of the red cells to be used for preparation of the particular type of hemoglobin solution under discussion will, then, be very important in its effect on the properties of the solution Uncertainty as to the exact state at which a given batch of cells might be, necessitated the finer comparisons being made only from a single lot of cells

In the solutions to be described below, with the exception of that of figure 1, the procedure of preparation was as described above, with only the variations noted in each case None of the solutions with the exception of that of figure 8 contained hexose diphosphate

Figure 1 gives the aging at room temperature of a hemoglobin solution made by the method of Hamilton et al.<sup>1</sup> Methemoglobin accumulated steadily. Such solutions examined after one year at  $-10^{\circ}\text{C}$  showed no accumulation of methemoglobin over that of the original solution. After two years of storage at  $-10^{\circ}\text{C}$ , however, such solutions have from 30 to 50 per cent of their total pigment in the form of methemoglobin.

Figure 2 gives aging data of a typical solution prepared by the methods just described. In the lower curve the hemoglobin was completely reduced on the

FIG. 1—AGING OF A HEMOGLOBIN SOLUTION PREPARED BY THE METHOD OF HAMILTON ET AL.<sup>1</sup> AT ROOM TEMPERATURE

seventh day. At the time this particular study was made, the methemoglobin content was being determined at weekly intervals. Later studies with daily determinations have revealed no deviation from this curve. The upper curve demonstrates that during storage there was no loss in total pigment content. Examination of these solutions for the presence of reducing substances following conversion of the pigment to reduced hemoglobin has revealed a drop in reducing substances from the original 6 per cent to 0.3 per cent.

Figure 3 illustrates that when dextrose was used, both in washing the cells and in the final solution, but neither nicotinic acid amide nor ammonia were used, methemoglobin gradually accumulated and then disappeared with reconversion to reduced hemoglobin. If no dextrose was used, but both nicotinic acid amide and ammonia were used there was no reconversion of methemoglobin. If the cells were

FIG 2—AGING AT ROOM TEMPERATURE OF A HEMOGLOBIN SOLUTION PREPARED BY THE METHODS DESCRIBED ABOVE

 --- Grams per cent of total hemoglobin in the solution

FIG 3—EFFECT OF DEXTROSE ON THE AGING OF HEMOGLOBIN SOLUTIONS AT ROOM TEMPERATURE

— Aging data for a hemoglobin solution in the preparation of which dextrose alone was used and from which the stroma was removed without adjustment of pH  
 --- Cells washed in 1 per cent sodium chloride solution but the solution made up as usual  
 ..... Cells washed as usual but no dextrose added to the solution after washing  
 -.-.- No dextrose added at any stage of preparation

washed in salt solution but the final solution contained dextrose reconversion of methemoglobin was again seen. If the cells were washed with 6 per cent dextrose solution but the solution was made up in physiological salt solution reconversion was slow and partial. These data indicated to us that the presence of dextrose in the final solution was essential, and its presence in the wash water desirable. It is interesting to note that maintenance of the cells and the hemoglobin con-

FIG. 4.—EFFECT OF NICOTINIC ACID AMIDE ON AGING OF HEMOGLOBIN SOLUTIONS AT ROOM TEMPERATURE

— Aging data for a solution made without addition of nicotinic acid amide at any stage  
 - - - - - 0.075 per cent nicotinic acid amide in final solution  
 - - - - - 0.15 per cent nicotinic acid amide in final solution  
 ——— 0.3 per cent nicotinic acid amide in final solution

stantly in the presence of dextrose alone will bring about reconversion of the methemoglobin. Three lots of cells were used in these preparations.

Figure 4 shows the effect of nicotinic acid amide on reconversion of methemoglobin to reduced hemoglobin. The upper curve shows aging data from a solution made without nicotinic acid amide at any stage. Reconversion of the methemoglobin formed was slow and incomplete. The three curves at the bottom of this graph represent a single hemoglobin solution, divided into 3 portions to which 0.075 per cent, 0.15 per cent and 0.3 per cent nicotinic acid amide were added respectively. Although as seen from figure 3 dextrose is essential, the efficacy of nicotinic acid amide is self evident.

Figure 5 The solid curve represents aging data obtained with a hemoglobin solution in which the neutralization of hydrochloric acid and adjustment to pH 7.3 was achieved with ammonium hydroxide. Neutralization with sodium hydroxide and the addition of ammonia was also effective. The two higher curves represent neutralization with sodium hydroxide and potassium carbonate with no ammonia addition. While not essential, ammonia is obviously advantageous to reconversion

FIG 5—EFFECT OF AMMONIA ON THE AGING OF HEMOGLOBIN SOLUTIONS AT ROOM TEMPERATURE

- Hemoglobin solution adjusted from pH 5.8 to pH 7.3 with ammonium hydroxide
- - - Hemoglobin solution neutralized with sodium hydroxide and 0.006 per cent ammonia added
- · - · Hemoglobin solution neutralized with sodium hydroxide no ammonia added at any stage
- Hemoglobin solution neutralized with potassium carbonate no ammonia added at any stage

of methemoglobin to hemoglobin. Curves in which an attempt was made to evaluate the optimum amount of ammonia all coincided with the base line, and are not shown.

Figure 6 The use of an ion exchange agent made it seem likely that traces of metals essential to some of the enzyme systems might be removed.  $Mg^{++}$  and  $Mn^{++}$  ions are well known to be important to the action of some enzymes and it has been suggested<sup>11</sup> that  $Mg^{++}$ ,  $Mn^{++}$  and  $Co^{++}$  may have protective action against certain types of inhibition of enzyme systems. The central curve represents aging data obtained with a solution to which no metal ions were added. The dotted line represents another portion of the same solution to which  $Mg^{++}$ ,  $Mn^{++}$  and  $Co^{++}$  ions

were added. Reconversion was much quicker in this solution. To separate vials of the control solution, sterile solutions of manganese chloride alone, cobalt chloride alone and magnesium sulfate alone were injected. The aging data were similar for

FIG 6—EFFECT OF  $Mg^{++}$ ,  $Mn^{++}$  AND  $Co^{++}$  IONS ON THE AGING OF HEMOGLOBIN SOLUTIONS AT ROOM TEMPERATURE.

- Hemoglobin solution containing no added  $Mg^{++}$ ,  $Mn^{++}$  or  $Co^{++}$  ions  
 ----- A portion of the same hemoglobin solution with 0.1 millimole of  $Mg^{++}$ ,  $Mn^{++}$  and  $Co^{++}$  added  
 -.-.-.- A portion of the same hemoglobin solution with 0.1 millimole of  $Co^{++}$  added

FIG 7—EFFECT OF NILE BLUE ON THE AGING OF HEMOGLOBIN SOLUTIONS AT ROOM TEMPERATURE

- Hemoglobin solution containing no nile blue  
 -.-.-.- A portion of the same hemoglobin solution containing 0.001 per cent nile blue

each set and are represented by the solid line curve. The long lag period preceding the appearance of methemoglobin was unexpected and its significance is not apparent to us.

Figure 7. A hemoglobin solution was made containing no nile blue. To one portion of this solution nile blue was added. The results are evident from this graph.

FIG 8—EFFECT OF HEXOSE DIPHOSPHATE ON AGING OF HEMOGLOBIN SOLUTIONS AT ROOM TEMPERATURE

— Hemoglobin solution containing no hexose diphosphate

----- A portion of the same solution containing 0.1 per cent of hexose diphosphate

FIG 9—EFFECT OF FILTRATION ON AGING OF HEMOGLOBIN SOLUTIONS AT ROOM TEMPERATURE

— Filtered through an S-6 pad

----- A portion of the same solution filtered through an S-3 pad

The ratio solution filtered/pad surface area, was identical for the two filtrations

Figure 8 As noted above hexose diphosphate has been incorporated in some of the more recent hemoglobin solutions. This figure shows aging data obtained with a solution to one portion of which hexose diphosphate was added. This portion

demonstrated a somewhat more active reconversion of methemoglobin than did the portion not containing hexose diphosphate

Figure 9 demonstrates the importance of the type of filter pad used for sterilization of hemoglobin solutions. A hemoglobin solution was divided before sterilizing filtration, one portion being filtered through a Republic S6 pad and one portion being filtered through the finer meshed Republic S3 pad. The ratio of the volume of hemoglobin solution filtered to the pad surface was identical for each portion. It can readily be seen that the tighter pad removed something from the solution that was important for the reversion of methemoglobin to hemoglobin.

### DISCUSSION

It has been reported by all previous workers that the ability of the erythrocyte to utilize dextrose as a substrate is lost at the time of, or soon after, the disruption of the cell.<sup>4, 43, 48, 50, 53, 64, 68</sup> The present data suggest that these previous findings must be qualified, for if the cells are maintained in the presence of dextrose during hemolysis, the ability to utilize dextrose continues. It is true that when the only precaution taken is maintenance of the cells in the presence of dextrose the utilization of dextrose after removal of the stroma is extremely slow. When, however, ammonia, a known stimulant of respiration,<sup>69, 70</sup> and nicotinic acid amide, a known protector of enzymic action,<sup>71</sup> are also present, utilization of dextrose and consumption of oxygen are appreciably accelerated. In the presence of dextrose, nicotinic acid amide and ammonia the additional contributions of added metals, nile blue and hexose diphosphate to the speed of consumption of oxygen from the solutions is relatively slight. The data suggest that the success of the preparation of the type of hemoglobin solution under discussion is dependent on the maintenance of as high a state of metabolic activity as possible in the red cell during the preparation. This approach may well lead to the development of solutions of still higher activity. One definite limitation to the activity of such solutions is suggested by the past emphasis on the importance of the cell structure for the activity of the cellular enzymes.<sup>53, 64, 66, 68</sup> The data in figure 9 give indication that some of the structurally important elements are necessary to the highest activity and can be removed by further treatment.

The respiratory activity of the adult mammalian red cell is known to be small. It was first clearly demonstrated by the use of dyes of proper oxidation-reduction potential.<sup>65, 7, 75</sup> Methylene blue, the dye most studied in this connection, not only catalyzes the action of the cellular enzyme systems but also catalyzes the formation of methemoglobin from hemoglobin. Kiese<sup>48</sup> pointed out that nile blue acted as a catalyst for the enzyme systems but did not catalyze the other reaction. It was used in these studies for that reason.

Since the entire cell residues from plasma have been used in these studies, it cannot be stated with accuracy that the white cells do not contribute to the self-reduction noted. The work of Bird<sup>76</sup> suggests that their contribution would not be a major one.

Although the solutions under discussion readily utilize dextrose as a substrate, the fact that added hexose diphosphate further increases the rate of disappearance

of oxygen is of importance since aging studies have indicated that the appearance of the reduced solutions improves in inverse proportion to the time of reduction.

The presence of specific enzymes capable of bringing about the actions observed has not been proven in this study. The factors affecting the data reported are highly suggestive that this action is enzymic, however. It is hoped to pursue this study further at a later date. It is also hoped to find something of the nature of the by products formed.

### SUMMARY

It is possible to prepare self-stabilizing solutions of hemoglobin from human erythrocytes by the use of dextrose, nicotinic acid amide and ammonia during the preparation and in the final solutions themselves.  $\text{Co}^{++}$ ,  $\text{Mn}^{++}$  and  $\text{Mg}^{++}$  ions, Nile blue and hexose diphosphate contribute to the speed of stabilization of these solutions. Stabilization is obtained by the faculty of the solutions, presumably by enzymic action, to convert the hemoglobin to the reduced form and to maintain it in this form. The hemoglobin solutions described are suitable for intravenous administration.

### ACKNOWLEDGMENT

We wish to acknowledge our deep indebtedness to Miss Lois Priester and to Mr. Edward Smith for their technical assistance in this work. We wish also to express our gratitude to the Biological Production Division and to the Biological Control Division of Sharp and Dohme for assistance in many phases of the work.

# THE EFFECT OF COBALT ON THE OXYGEN CAPACITY AND THE METHEMOGLOBIN CONTENT OF THE BLOOD

By MARY C. BUCCIERO, M.S., AND JAMES M. ORTEN, Ph.D.

ONE THEORY as to the mechanism of the production of polycythemia in the rat, and several other species, by cobalt, is that this substance interferes with cellular oxidative processes.<sup>1,4</sup> One way in which such an effect might be produced would be by an interference with the transport of oxygen in the blood to the cells either by a decrease in the oxygen capacity of hemoglobin itself or by the formation of methemoglobin possibly containing cobalt in place of iron. In the present investigation a study was made of the oxygen capacity and the methemoglobin and cobalt content of the blood of rats which had been maintained in a state of polycythemia by cobalt administration for a period of at least six weeks.

## EXPERIMENTAL

Male, weanling, albino rats Connecticut Agricultural Experimental Station strain, were used. They were fed an adequate synthetic basal diet described in a previous publication.<sup>2</sup> Various supplements were added to the basal diet in amounts also described in detail in the above paper. The groups studied included a control group and groups given cobalt alone (477 mg recrystallized  $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$  per kilo of diet), or cobalt supplemented with either choline (2.0 Gm choline chloride per kilo of diet), or cysteine (1.56 Gm L-cysteine hydrochloride per kilo of diet). The latter two groups of animals were part of a different study to be reported later. The amount of cobalt sulfate added to the diet supplies each rat with approximately 1.0 mg cobalt per day, an amount found in previous studies to produce a definite polycythemia in the rat. After the animals had been on experiment for a period of twenty weeks and the cobalt-treated rats had developed the characteristic polycythemia, with the exception of those given cysteine, as will be described in a subsequent publication, they were sacrificed and samples of blood were taken for analysis in the following manner. The animals were anesthetized with ether and five to eight ml of blood was drawn from the heart into tubes containing heparin. Of this amount, a very small portion was used for the total hemoglobin determination by the acid hematin method using the Coleman spectrophotometer. One ml was used for the determination of oxygen capacity, 1 ml for the estimation of methemoglobin, and the remainder was reserved for a spectrographic analysis\* for cobalt. The method used for the determination of the oxygen capacity of the blood was Sendrov's modification using the Van Slyke-Neill manometric appa-

From the Department of Physiological Chemistry Wayne University College of Medicine, Detroit.  
The data in this paper were taken from a dissertation presented by Mary C. Bucciero in partial fulfillment of the requirements for the degree of Master of Science, Wayne University, 1948.  
A preliminary report was made before the American Society of Biological Chemists at the Chicago meeting, May 1947.

Acknowledgment is expressed to Dr. Virginia Sink of the Research Laboratories, Chrysler Corporation, Detroit, for running the spectrographic analyses of the samples.

ratus.<sup>3</sup> The methemoglobin content of the samples was determined by a colorimetric procedure outlined in Kolmer and Boerner.<sup>3</sup> The remainder of the blood was carefully ashed and a spectrographic analysis for cobalt was made.

### RESULTS AND DISCUSSION

In Tables 1 and 2 are recorded the average terminal hemoglobin values, as determined by the acid-hematin and oxygen-capacity methods, and the average methemoglobin content of the blood of the various groups of animals. It is evident from the data in the two tables that there is a close correlation between the hemoglobin values by the two methods and that there is no significant amount of methemoglobin present in the blood of the cobalt-treated rats. The greater variations from

TABLE 1.—Terminal Hemoglobin Values of Control and of Cobalt-treated Rats

Group	Number of rats	Hemoglobin—Gm. %			
		Acid Hematin Method		O <sub>2</sub> Capacity Method	
		Average	Standard Deviation	Average	Standard Deviation
Control	8	15.4	±0.4	15.5	±0.5
Cobalt	8	19.7	±1.9	19.7	±2.1
Cobalt + Choline	7	19.2	±1.4	19.6	±1.3
Cobalt + Cysteine	8	17.4	±1.7	17.1	±1.5

TABLE 2.—Methemoglobin Content of Blood of Control and Cobalt-treated Rats

Group	Number of Rats	Total Hemoglobin Average Gm. %	Active Hemoglobin (by O <sub>2</sub> Capacity) Gm. %	Methemoglobin	
				Gm. %	Range
Control	8	15.3	15.6	-0.3	0.0 to -1.3
Cobalt	8	20.8	19.6	+1.2	+2.8 to -1.9
Cobalt + Choline	7	19.2	19.6	-0.4	+1.4 to -2.6
Cobalt + Cysteine	7	18.7	17.1	+1.6	+2.2 to 0.0

the average in the terminal hemoglobin and methemoglobin values observed in the cobalt-treated rats, as compared with the controls, appears to be a result of greater difficulties in obtaining and measuring blood samples in the former groups. The blood of the rats given cobalt was extremely viscous. The spectrographic analyses of the ashed blood samples showed no more than trace amounts of cobalt in any specimen.

The foregoing observations together thus constitute evidence that the mechanism of the production of polycythemia by cobalt is not one of the formation of an altered type of hemoglobin having a decreased oxygen-carrying capacity, nor can it be attributed to the formation of methemoglobin. Further substantiation of this view is afforded by the results obtained in the spectrographic analysis for cobalt which demonstrated the absence of more than a trace of that element in the blood. This latter observation is in agreement with that of Stare and Elvehjem<sup>6</sup> who found

only traces of cobalt in the blood of cobalt-treated polycythemic rats by a colorimetric method using nitroso-R-salt

### CONCLUSIONS

A study has been made of the oxygen capacity and the methemoglobin and cobalt content of the blood of rats administered approximately 1 mg cobalt daily for twenty weeks, in order to produce a sustained polycythemia.

No evidence of a decrease in the oxygen capacity of the blood of the cobalt-treated polycythemic rats was found, nor did the methemoglobin content differ significantly from the small amount found in the blood of control rats. No more than traces of cobalt were found in the blood of either group by spectrographic analysis.

These observations are interpreted as evidence that the mechanism of the production of polycythemia by cobalt is not one of lowering the oxygen capacity of hemoglobin nor of producing a methemoglobin, possibly containing cobalt rather than iron in the hemoglobin molecule.

## EDITORIAL

### TRACE METALS IN BLOOD, WITH PARTICULAR REFERENCE TO ZINC AND CARBONIC ANHYDRASE

THE PHYSIOLOGIC role of the trace metals was neglected in biochemical investigations of the blood in the last decade, but recently interest has been aroused in their function in blood formation. The term trace metals is unfortunate in that it has carried the implications that these elements cannot be measured quantitatively, that they probably occur accidentally, and that their presence is of no discernible consequence.

The development of precise microchemical methods has given the whole study new impetus even though many of these methods are complex and difficult. The needs of industry have given rise to the formulation of excellent colorimetric, flame photometric, polarographic, and emission spectroscopic techniques, which are accurate for the measurement of very small quantities of elements, provided the necessary precautions regarding scrupulous cleanliness and avoidance of contamination of reagents and glassware are observed. Although the availability of radioactive isotopes has further stimulated interest in the field, it is erroneous to conclude that these substances serve their greatest usefulness in replacing microchemical techniques, actually, the two serve best as mutually interdependent but supplementary approaches.

The investigation of iron metabolism has been for years an important part of hematologic research. The association of iron with hemoglobin and porphyrin pigments lends itself readily to spectrophotometric analysis, thus making it a rewarding subject for study, especially during periods when good microchemical techniques for iron itself were not available. Knowledge concerning its metabolism is therefore developed to a degree unique among the metals. On the other hand, the relation of iron to the function of cytochromes, catalase and peroxidases in the erythrocyte is not established although it is known that these enzymes contain iron. Earlier physiologic work on cobalt and polycythemia<sup>1</sup> has been re-examined recently in the light of new data on anemias, particularly in relation to vitamin B<sub>12</sub>, a cobalt-containing complex. After previous work,<sup>2</sup> copper, too, is being studied in relation to regeneration of hemoglobin and in regard to its role in the hemocuprein found in red blood cells.<sup>3</sup> These elements are the only ones to have been studied with any degree of thoroughness. That titanium or vanadium are possible constituents of erythrocytes arouses no more than mild curiosity, although there is no reason for such an attitude other than the lack of information.

Available facts favor the assumption that many of the trace elements serve their function in association with protein molecules bound by S-H, COOH, NH<sub>2</sub>, or porphyrin groups. These proteins may be involved in hormone or enzyme systems (including vitamins) or may serve in functions of storage or transport. These metallo-enzyme systems are now receiving an increasingly large amount of attention.

An example of the rapid development of knowledge regarding a trace element is afforded by zinc, recent studies in the distribution and physiologic role of zinc are the result of advances in the chemistry of the rarer biologic elements and in nuclear physics and enzyme chemistry. It has been found that Zn is a constituent of human blood and is found in corpuscles and plasma. These studies were stimulated by the finding that Zn is more concentrated in leukocytes than in erythrocytes, as revealed by emission spectrography.<sup>5</sup> Subsequently, measurements have been made by means of a colorimetric technic<sup>6</sup> which is accurate to one microgram. The normal mean whole blood Zn level for males and females is 880 micrograms per cent, the normal mean plasma Zn 300 micrograms per cent, and 100 cc of packed erythrocytes contain 1440 micrograms.<sup>7</sup> Overall, 75 per cent of the whole blood zinc is found in the red cells, 22 per cent in the plasma and 3 per cent in the leukocytes separated from whole blood by a method based on physical chemical principles.<sup>8</sup> While a greater fraction of the total blood Zn is contained in the erythrocytes, cell for cell the leukocytes contain 25 times as much as the erythrocytes. Statistical analysis of the data suggest that zinc is a physiologic constituent of blood in that its individual variations in concentration follow the pattern of commonly observed biologic distribution phenomena. Actually, the metal occurs in quantities in the body which in modern biologic language can hardly be called traces.

Injection of radioactive  $^{65}\text{Zn}$  demonstrated its incorporation into the red and white blood cells of dog and man where it could be found as much as eight months after injection. Its passage across the placenta of the dog into the young has also been shown,<sup>9</sup> and might indicate its physiologic need.

The nature of the protein to which Zn is bound in plasma is unknown at present, although preliminary investigations<sup>10</sup> have shown that the metal becomes attached to the iron binding globulin<sup>11</sup> in vitro. However, it is not known whether this is the transport mechanism in the body.

The role of zinc in leukocytes is a mystery at present. Its differential distribution among the various groups of white cells has not been studied. Attempts at radioactive tagging in order to study the leukocytic life span have at best been inconclusive. The possible occurrence of exchange of zinc across the white cell membrane contributes to the difficulties of interpretation, and, most important of all, the nature of the compound with which Zn is associated in the leukocyte is unknown. The decrease of Zn in the peripheral leukocytes of patients with chronic myelocytic, lymphocytic and monocytic leukemia is, however, a startling abnormality. The concentration of zinc in the leukocytes of these patients is approximately 10 per cent of that found in normal leukocytes. Under therapy with x-ray or urethane and in clinical remission, the falling leukocyte count is accompanied by a rise of zinc to normal levels. Attempts at raising the Zn level of these cells and lowering the leukocyte count by injections of stable zinc gluconate have not been successful.<sup>1</sup> Whether leukemic cells are Zn deficient because they are immature, or whether they are leukemic because they are Zn deficient is difficult to evaluate at present. However, investigations of mouse epidermis<sup>12</sup> have shown a decrease in

Zn and other elements as neoplasia developed. This is at least a clue to the fact that there is a rearrangement of the rarer elements in neoplastic tissues. It is evident that it will be necessary to study all of the minor elements in leukemic cells before any conclusions concerning the true meaning of the decreased Zn content may be drawn. Unquestionably, however, studies of Zn metabolism offer a new approach to leukopoiesis.

More is known concerning zinc in erythrocytes. Keilin and Mann<sup>14</sup> recorded the presence of that element in the enzyme carbonic anhydrase, shown earlier by Meldrum and Roughton<sup>15</sup> and by Stadie and O'Brien<sup>16</sup> to be contained in the red blood cell. The enzyme has a molecular weight of approximately 30,000 and contains 0.3 per cent zinc. The functional significance of the zinc in the molecule is shown by the fact that removal or inactivation of the metal by trichloroacetic acid or by BAL<sup>17</sup> also inactivates the enzyme. The enzyme catalyzes the reaction  $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$  which otherwise would proceed at too slow a rate to permit life in mammals or birds. It is evident that carbonic anhydrase may be as important in carbon dioxide transport as hemoglobin is in oxygen transport, yet the former has not been investigated thoroughly. Studies of the enzyme in human and dog blood have shown that all the activity is in the erythrocytes. There is none in plasma or leukocytes. *It is evident, therefore that zinc exists in blood in several states.*

The carbonic anhydrase content and Zn concentration of the red cells parallel each other and vary directly with the hematocrit level and the hemoglobin concentration in congestive failure, anemia and polycythemia.<sup>18-22</sup> It is of unusual interest, however, that in pernicious anemia the erythrocyte zinc concentration and blood carbonic anhydrase activity are in or close to the normal range despite low hematocrit, cell percentages and hemoglobin values, the mean corpuscular zinc concentration and carbonic anhydrase activity are increased several times more than the high mean corpuscular hemoglobin and out of all proportion to the increase in cell size. Normal findings develop in remission in a period of time commensurate with the known mean life span of pernicious anemia red cells, evidently as a result of their being replaced by normal cells.<sup>19-22</sup> In other clinical conditions such as the postnatal state in infants,<sup>23</sup> the sickling phenomenon<sup>21</sup> and paroxysmal cold hemoglobinuria<sup>25</sup> studies of the carbonic anhydrase system suggest a role of the enzyme in their mechanisms.

Although the above findings relating to disturbances in enzyme activity and zinc concentration in various conditions are of interest, their significance cannot be stated. At present, sufficient data are not available on the physiology of carbonic anhydrase to make possible a definition of its precise function in the blood. Thus, although it is known what the enzyme can do, what it actually does is not known. However, the observation that a close parallelism exists between the erythrocyte carbonic anhydrase activity and zinc content in all conditions studied<sup>19</sup> provides a useful method for estimating the amount of the enzyme in the red blood cells, apparently all the zinc in erythrocytes is part of the carbonic anhydrase molecule.

The present data bearing on zinc in the blood, although incomplete, call atten-

tion to the even larger gaps which exist in knowledge of other erythrocyte metals and metallo-enzyme systems

### PREFACE

#### BLOOD CELLS AND THEIR REACTIONS

TWO YEARS AGO, a special issue of *Blood*, Morphologic Hematology, was published. At that time *Blood* was a bimonthly publication, and purchase of this special issue placed an extra burden upon the interested subscriber. This was criticized sharply, and as a result it was determined that in the future, all special issues should be sent to regular subscribers without extra cost. The present issue represents the first application of this principle. The excess in cost above the publication charge for a regular issue has been borne by a very generous grant from the Lederle Laboratories Division of the American Cyanamid Company.

Despite the startling advances made in the physiologic and chemical aspects of hematology, the base line of that specialty must still remain the cell. The reactions of the blood cells, their enzymatic constituents, their chemical reactions are now being actively studied by such techniques as those of histochemistry and phase microscopy. In fact, the cytologist, far from having lost ground, is now in an enviable position. From the appearance and reactions of a cell when subjected to various chemical reactions, it is possible to interpret in some measure its complicated functions, and from this it is only a short step to phenomena of abnormal growth such as leukemia and leukosarcoma. The ultimate control of such highly proliferative diseases will come only through a knowledge of the complicated growth problems of the white cells.

In the past several months, a large number of manuscripts devoted to blood cells has been accepted for publication in *Blood*. In this issue, many of them are arranged together in broad sections dealing with the red cells, the leukocytes, and the platelets. It is hoped that this symposium of blood cells and their reactions will prove of value and will serve as a convenient reference to some of the modern phases of morphologic hematology.

WILLIAM DAMESHEK  
for the Editors of *Blood*

# THE CHEMISTRY AND FUNCTIONING OF THE MAMMALIAN ERYTHROCYTE

By S GRANICK, PH D

## INTRODUCTION

THE ERYTHROCYTE has been one of the most intensively studied of cells. Much of the data, however, remains isolated in specialized fields. It was with the intention of bringing together and correlating some aspects of these specialized fields that this review was undertaken. If it can serve to indicate the complexity and beauty of design of this bit of protoplasm as a unit, as well as in its constituent parts, it will have been worth-while.

## I DEVELOPMENT OF THE RED CELL

*Technic of Cytochemistry* The recent advances in the study of red cell development are due mainly to the newer technic of cytochemistry. The cytologist has for a long time made skillful use of various dyestuffs to study the changes in staining of particular regions of cells and to observe the changing staining capacities in the differentiation of the cells. Within recent years, interest has centered on the interpretation of staining in terms of the affinity of dyestuffs for special chemical groupings of substances. As might be expected, the major forces in these staining procedures are of coulombic nature. Thus, for example, basic dyestuffs, like methylene blue or brilliant cresyl blue, carrying positive charges, appear to stain acidic substances, carrying negative charges such as the phosphoric acid groups in nucleic acid or the half-sulfuric acid ester groups of heparin.<sup>1</sup> Again, acidic dyes like eosin, with negatively charged groups, tend to combine more firmly with the positively charged basic groups like those on histones or on globin. Supporting techniques have now placed these interpretations of staining on a firmer foundation and also have extended our chemical knowledge of the cell substances. Among such supporting techniques has been the Feulgen staining for desoxyribose which has shown that desoxyribose nucleic acid is limited to the chromatin of the nucleus. The intense absorption of the purine and pyrimidine components of nucleic acid in the region of 2,600 Å has been utilized by Caspersson in an ingenious technic to determine the location of these substances in specific regions of a cell. The use of enzymes for digesting away specific substances has shown the localization of materials such as proteins, ribose nucleic or desoxyribose nucleic acid, etc., in fixed cells. Advantage has also been taken of the enzymic action of the cells themselves in order to determine the location and activity of regions containing the particular enzyme.<sup>2-3</sup> In addition, the dye-binding capacity over a range of pH may permit of the identification of proteins of high or low isoelectric points.<sup>4</sup> Detailed studies of the red cell using some of the absorption spectra techniques of Caspersson<sup>5</sup> have recently been reported in a monograph by Thorell.<sup>6</sup>

From the Laboratories of The Rockefeller Institute for Medical Research, New York, N. Y.

*Cytochemistry of Red Cell Development* The transformation of a reticular cell of the bone marrow—a rather nondescript kind of a cell, relatively small, with a nucleus poor in chromatin—into the mature red cell, is brought about by the little understood processes of nucleic acid metabolism, of protein synthesis and of differentiation. Such processes are not peculiar to the red cell, but the manifestation of these processes is perhaps more readily apparent in this cell than in other cell types. Although it will be possible to say little with certainty about these processes, it will be useful to examine the development of the red cell to see what inferences may be drawn about these processes in chemical terms.

In the following description of the changes in red cell development the major data have been derived from the studies of Sabin<sup>7</sup> and of Thorell. According to Sabin, reticular cells of the bone marrow endothelium, which develop in sinusoids temporarily closed to circulation, give rise to the erythrocytic series. On the other hand, those reticular cells which develop extravascularly give rise to the granulocyte series. If this interpretation of origin is a correct one, then we have here a most interesting example of differentiation.\* From a chemical point of view the mechanism of this differentiation might be studied most readily in tissue culture by examining the effect of nutrition and environment on the kind of cell type which would arise. A method for the culture of marrow has been developed by Osgood and Brownlee<sup>8</sup> and recently was modified by Plum.<sup>9</sup>

Once the presumptive proerythroblast has been established, three phases of growth to the mature erythrocyte may be distinguished (fig. 1). The first is a phase of rapid cell multiplication, then occurs a decline in growth rate. Finally, overlapping with this decline, a marked differentiation sets in, hemoglobin being synthesized concomitantly with a loss of other cytoplasmic proteins and desoxy-ribose nucleic acids.

The stem cell of the erythrocytic series, the proerythroblast, is a cell 12  $\mu$  in diameter, containing a moderate number of mitochondria, a golgi net, a cytocentrum and conspicuous nucleoli. The chromatin of the nucleus contains desoxy-ribosenucleic acid. The nucleolus and the cytoplasm contain only ribosenucleic acid. The cytoplasm at this stage is high in ribose nucleic acid containing about 5 per cent of its dry weight in this substance (fig. 1-A). The high content of ribose-nucleic acid runs parallel with the basophilic staining which is maximum in the proerythroblast. At this stage, the cells multiply rapidly and one may therefore infer that there is taking place intense protein and nucleic acid synthesis both in the nucleus and in the cytoplasm.

In the second stage, that is, in the early or basophilic erythroblast, the concentration of cellular protein is at a maximum (fig. 1-B) and this is also reflected in the curve for the product of the number of cells times the cell volume, which attains a maximum (fig. 1-C). The basophilic erythroblast has a diameter now of 10  $\mu$  (fig. 1-E) the ribose nucleic content of the cytoplasm has decreased to 2 per cent, the nucleus has lost its nucleoli and contains angular particles of chromatin.

In the late or polychromatic erythroblast the ribose nucleic acid has further

\* For details of differentiation in the evolution of the blood forming tissues the account by Jordan<sup>126</sup> is recommended.

diminished, paralleling the decreased affinity of the cytoplasm for basic dyes (fig 1-A) At the same time, the staining with acid dyes becomes significant, which has been considered as indicating the increase in the relatively basic protein globin (fig 1-B)

In general, the cytologist has assumed that this increased intensity of staining with acid dyes can parallel with the development of the hemoglobin color of the cell, this would mean that globin and heme synthesis occurred simultaneously. Measurements by Thorell, using the strong absorption band of heme at 4,000 Å,

FIG. 1—THE DEVELOPMENT, DIFFERENTIATION AND MATURATION OF THE ERYTHROCYTE (modified from Sabin and from Thorell)

Quantitative data are presented by the full lines; qualitative changes by the broken lines.

have clearly demonstrated the rapid development of heme and presumably hemoglobin during the polychromatophilic erythroblast stage, no further increase occurring in the normoblast stage. Thorell considers that the rapid synthesis of cellular proteins is intimately connected with a high ribose nucleic acid content, as exemplified in the first stage of development (fig 1-A). According to Thorell the high cellular protein which is found at the end of the first stage might be globin itself, heme would be added to form hemoglobin only after the late erythroblast stage. However, if in the early erythroblast stage, the globin content were high, the cell ought to be stainable with acid dyes, which it is not (unless perhaps the high nucleic acid in the cytoplasm could form some kind of a complex with the

globin to prevent acidic staining.) If it is assumed that the staining technic reveals the presence of globin, then it would appear that at a relatively late stage, in a cytoplasm rich in proteins, these proteins would be gradually replaced almost completely and exclusively by a single kind of protein, globin, that is, the curve of hemoglobin synthesis would also represent the curve of globin synthesis (fig 1-B)

In the normoblast or orthochromatic erythroblast of about  $7\mu$  diameter, cell divisions no longer occur. The nucleus has become small and pyknotic, mitochondria have disappeared, and only a trace of ribose nucleic acid remains in the cytoplasm. However, the hemoglobin concentration has increased from 1-2 per cent of the previous stage up to 20 per cent at the normoblast stage where it remains constant (fig 1-B), the cytoplasm now stains intensely with acid dyes as would be expected from its high globin content. This stage of the normoblast lasts about two days.<sup>10</sup> Some time after the loss of the nucleus, there occurs the flattening and appearance of biconcavity of the cell. Plum has recently claimed that the normoblasts give rise to mature erythrocytes by a process of budding off droplets of cytoplasm.<sup>11</sup>

In the reticulocytes the stroma of the cell is 2.5-4.5 times greater than in the normoblast. Such reticulocytes contain more lipid than do the mature red cells and their surface is stickier.<sup>10</sup> The reticulocyte is of slightly larger volume and lesser density than the mature red cell. Dustin<sup>12</sup> has demonstrated, using ribonuclease, that the reticulum contains ribosenucleic acid. The change from the reticulocyte to the mature red cell occurs in from one to three days. According to the investigations of Plum,<sup>11</sup> there appears to be a thermolabile 'unripe' substance, especially high in concentration in the mucosa of the fundus stomach, which when carried to the reticuloendothelial system is activated by tyrosine, resulting in the formation of a fully ripe maturing substance present in blood plasma. This maturing substance, acting on reticulocytes, is claimed to cause the disappearance of the reticulum.

Thorell has found that nucleated megaloblast cells in pernicious anemia have a high content (4-5 per cent) of ribosenucleic acid in the cytoplasm and also contain hemoglobin, the hemoglobin content increasing as the size of the cell decreases. This may be contrasted with the polychromatophile erythroblast where very little ribose nucleic acid is present in the cytoplasm and the hemoglobin is increasing rapidly.

Since the metabolic end product of the nucleic acid purines is uric acid, the rapid maturation of erythrocytes should be accompanied by an increase in excretion of uric acid. This is most readily observed in recovery from pernicious anemia where approximately 10 Gm uric acid are excreted in the urine for an increase in count of 1 million erythrocytes per cu mm. The increase in uric acid in the blood starts within twenty-four hours after the onset of treatment and the peak of the uric acid precedes the peak of reticulocyte production by twenty-four hours.<sup>13</sup>

As the red cell matures it differentiates into what is essentially a tiny bag,  $7\mu$  in diameter, containing hemoglobin. During the differentiation the cell loses its nucleus, and with it the ability to make desoxyribosenucleic acid. In the reticulocyte stage the last vestiges of ribosenucleic acid are seen as the reticulum, and at this time when the ribosenucleic acid disappears there has disappeared the ability to

synthesize hemoglobin and heme.<sup>14</sup> In the mature red cell very little oxygen is utilized for respiration (0.05–0.1 cc oxygen per mg dry weight per hour as compared with ten times this rate for the nucleated erythrocyte<sup>15</sup>). From this fact it may be inferred that some portions of the cytochrome oxidase system are absent or nearly so. According to recent findings,<sup>16</sup> the cytochrome oxidase enzymes are generally contained in mitochondria. The fact that mitochondria have disappeared from the mature red cell, therefore, correlates well with its low oxygen metabolism. Small but important concentrations of certain other proteins are present. For example, an enzyme system remaining in the mature erythrocyte is the glycolytic system which appears to be a rather complete one. This system serves to maintain the hemoglobin in the reduced or functional ferrous state. In addition, catalase is present to protect the heme from peroxide decomposition and carbonic anhydrase is present to aid in the transport of  $\text{CO}_2$  as bicarbonate ions.

## II COMPOSITION OF THE WATER INSOLUBLE CONSTITUENTS, I E., THE STROMA

When red cells are hemolyzed, the soluble constituents flow away and there remains an insoluble residue of ghosts, the membranes of which have a thickness of some 200–300 Å. This material constitutes about 2–5 per cent of the wet weight of the original cell. Of the stroma material, some 40–60 per cent is insoluble protein and some 10–12 per cent is lipid.<sup>17, 18</sup> A method for the preparation of the stroma has been described by Parpart.<sup>19</sup>

*Properties of the Red Cell Surface.* Various properties, such as hemolysis with many different substances, selective permeability to anions, blood group materials, virus affinities, etc. indicate that the stroma is a complex or mosaic structure derived not only from the red cell proper, but also to some extent accumulated by accretion. The red cell is a reagent of great sensitivity for the detection of various substances if these substances can bring about agglutination or hemolysis. This sensitivity results from the fact that only relatively few discrete areas or specific groupings on the relatively large surface of the red cell need to be acted upon in order to observe hemolysis or agglutination. However, it has not been possible as yet to infer from the action of many of these reagents what specific groupings of the red cell membrane may be involved.

A subject of great interest at present is the mechanism by which some animal viruses bring about the agglutination of some species of red cells. For example, Hirst<sup>20</sup> first found that the influenza virus brings about the agglutination of human and chick red cells, and Horsfall et al.<sup>21</sup> have described the agglutination of mouse or hamster red cells by the pneumonia virus of mice. On chick red cells the receptor areas for influenza virus were found to be very stable to treatment with relatively high temperatures and with a number of reagents, but they were inactivated by proteolytic enzymes, by periodate, as well as by several hours contact with the influenza virus itself, (i.e., the virus appeared to possess enzymic activity). It was concluded that protein seemed to be an essential constituent of this receptor. According to Hirst, in the IV-4 fraction of normal serum, a  $\beta$  globulin is present, having certain properties which are similar to those of the receptor spot and this substance does not have the properties of a mucin. De Burgh et al.<sup>22</sup> have prepared,

from the erythrocytes, extracts which contain at least 50 per cent of polysaccharide and which are capable of inhibiting specifically the hemagglutinating action of the virus. The effect is presumably due to competitive combination of this extract with the virus. The virus appears to act on this extract, possibly enzymatically, as it does on the red cell surface, i.e., on prolonged contact of virus and the extract a change occurs in the extract so that it no longer binds the virus. The influenza inhibitor has also been obtained from human lung. If the virus is heated, agglutination of the red cells still takes place but the enzymic activity seems to be destroyed. It may be postulated either that the chemical groupings necessary for agglutination are destroyed by the enzyme or that the enzyme activity brings about new groupings which interfere with the groups taking part in the agglutination. Hanig<sup>22</sup> has found that the electrokinetic potential of a human red cell is maximally depressed when about 300 influenza virus particles coat the cell, covering only about one-eightieth of the surface. Ordinarily, the electric mobility of the red cell remains unchanged in the presence of various proteins, including even the anti-sphering protein of Furchgott.

Hemolysis, the escape of hemoglobin from the red cell under isotonic conditions, may be brought about by changes in different regions of the cell surface.<sup>15</sup> For example, surface active agents such as digitonin, saponin, lysolecithin, etc., may dissolve out fatty materials or may denature proteins in the cell surface, leaving holes sufficiently large for the hemoglobin molecules to diffuse out. Such agents may be effective in concentrations lower than would be needed to form a single monolayer on the surface. Still more effective agents are the specific immune bodies such as the agglutinins and hemolysins.

The hemolysins may react with the red cell to cause hemolysis directly. More commonly, hemolysis appears to be brought about indirectly. For example, adsorption of agglutinins apparently leads to some kind of injury to the cell surface, the agglutinated cells becoming mechanically more fragile, final hemolysis is then brought about rapidly by complement or more slowly by mechanical trauma.<sup>24</sup> Brunius has calculated that some 30 antibody molecules would be sufficient to sensitize a red cell so that when some 6,000 molecules of complement are added, the cell hemolyzes. Sensitization or agglutination may also be brought about by non specific substances such as silicic acid, tannin, or the protein conconavalin A, here too, there is an increase in mechanical fragility, and the addition of complement also results in hemolysis. The complexity of this phenomenon is illustrated by the complexity of the composition of complement. Complement appears to be a mixture of euglobulin, two mucoproteins, and a heat stable compound containing phosphorus. All of the components of complement must attach in the proper order before hemolysis will occur.<sup>25</sup>

Another illustration of surface specificity is suggested by the phenomenon connected with a cold hemolysin.<sup>26</sup> For hemolysis of red cells to occur in cold paroxysmal hemoglobinuria, a hemolysin and components of complement are required. When the cells are chilled, the hemolysin and a component of complement are adsorbed simultaneously. Then on warming, hemolysis will occur, but only if another component of complement (a heat-labile component) is present. In one case,

if the chilling of the red cells occurred in the presence of either sulfanilamide or cyanide, hemolysis did not take place on subsequent warming. It could be shown that these reagents had not prevented the adsorption of hemolysin or complement. After dialyzing away the cyanide or sulfanilamide hemolysis occurred. In this case, the cold hemolysin and complement appear to be absorbed in the immediate vicinity of a molecule of carbonic anhydrase which is poisoned specifically by cyanide or sulfanilamide. The attachment of either of these reagents presumably at the zinc atom of the carbonic anhydrase prevented the lysis of the red cell.

A recent interesting interpretation of the ultrastructure of the ghost is that of a meshwork of tangentially arranged, long fibrous protein molecules, each being surrounded by about one hundred lipid molecules which are oriented radially around the fibrous protein.<sup>27</sup> It is not possible to decide as yet whether the ghost is balloon-like and hollow inside, or whether it contains a gel-like interior. If the stroma substance is present at all in the interior, it is probably very low in concentration. In isotonic saline, the ghost is a biconcave disc even after extraction of the lipids,<sup>28</sup> so the principal shape factors of the red cell may normally be considered to reside in the protein structure of the ghost. Waugh and Schmitt<sup>29</sup> have shown that the central region of the ghost, corresponding to the biconcavity, is thicker in protein by 30–40 Å than is the region near the edges of the ghost. In the classic work on the isoelectric point of hemoglobin, Michaelis and Takahashi<sup>30</sup> reported that hemolyzed red cells, in which excess hemoglobin was not washed away, had an agglutination optimum of pH 5.0 for all species investigated, suggesting that the isoelectric point of the stroma proteins might be at this pH. Since hemoglobin is found to leak out of a red cell immersed in a solution below pH 5.0, they hypothesized that when the pH was below 5.0 the stroma would have a positive charge, and only then would hemoglobin leak out.

**Lipids.** The lipids constitute about 0.4 per cent of the fresh weight of the human red cell and over 90 per cent of this material is present in the stroma substance. Some 33 per cent of the lipid is cephalin, 21 per cent is lecithin, 20 per cent is cholesterol, 5 per cent is made up of cholesterol esters, 3 per cent is neutral fat and 9 per cent is made up of the cerebroside.<sup>18</sup> For lyophilized human red cells Hack<sup>31</sup> reports phosphatide values per liter of red cells as: total phosphatide 3.05 Gm, cephalin 1.25 Gm, lecithin 0.92 Gm, sphingomyelin 0.88 Gm. Cephalin is the largest phospholipid fraction in the cells and the sphingomyelin concentration of the cells is twice that of the plasma. According to Parpart,<sup>32</sup> about 40–60 per cent of the lipids are bound to the stroma proteins, there being considerable variation in the different species.

Ballentine and Parpart<sup>33</sup> have found that pancreatic lipase acting on beef or rabbit erythrocytes at pH 5.0–5.5, increases the rate of penetration of ethylene glycol and glycerol, i.e., substances which are considered to enter the cell surface by way of aqueous channels. They have postulated that the lipase probably splits off one fatty acid residue per phospholipid molecule, but the fatty acids thus split off remain bound to the surface. They suggest that the phospholipid portion of the surface and the orientation of this lipid material form an architectural unit in the structure of the aqueous channels.

*Proteins* The insoluble protein constituent of the stroma, the stromatin, has properties of solubility resembling those of the albuminoids. It is rapidly digested by crude trypsin or by activated papain preparations, although the intact erythrocyte itself does not appear to be affected by crystallin trypsin.<sup>33</sup> As compared with globin, the stromatin is lower in histidine and lysine but higher in arginine. It contains 2.1 per cent histidine, 5.0 per cent arginine and 3.6 per cent lysine.<sup>34</sup>

An anti-sphering protein, which is in part responsible for the maintenance of the disk shape of the red cell, has been identified by Furchgott and Ponder,<sup>35</sup> as a fraction of serum albumin poor in carbohydrate. Red cells may be freed of this protein by adsorption of the protein on glass surfaces. Normally, at a pH above 11.3, but not below this pH, the red cell will become spherical. If, however, the antisphering protein has been removed, the red cell will become spherical at pH 9.2 or above. Addition to such a spherical cell of serum or plasma containing the antisphering protein will restore it to the disk shape, that is, the phenomenon is reversible. Ghosts which do not have the antisphering protein only sphere once, at pH 9.2, and almost immediately go spontaneously again to the disk shape, and the phenomenon is not reversible. These results explain the sphering of the red cells often observed when viewed in saline between somewhat alkaline coverslips. The quantity of this protein taken up by the spherized cells to bring them back to normal shape is sufficient to form a layer of some 50 Å at the surface. The adsorption of this protein does not appear to change the electrokinetic properties of the cell.

Calvin and co-workers<sup>36</sup> have recently reported the isolation of a lipo-protein complex 'elinin', which is said to constitute 40 per cent of the stroma substance, the remainder being 'stromatin'. The stromatin N is 12.3 and P 0.42, the elinin N is 9.1 and P 1.0. Elinin was isolated from cold, washed, human ghosts at pH 7-8 by centrifugation at 50,000 G, the stromatin remaining in solution. Elinin dissolves readily at pH 7-8 to give a milky solution with marked streaming birefringence. It contains about 40-50 per cent of lipids extractable with 3:1 alcohol. The Rh antigen was found to be solely in the elinin fraction, and the content of A and B antigens was four to five times higher in this fraction than in the stroma substance. The Rh antigen is particularly sensitive to thermal inactivation, being destroyed by exposure to 56°C for a few minutes. The A and B antigens are, in contrast, rather heat stable. An ether soluble fraction has been separated from elinin which contains a still higher content of Rh antigen.

*Blood Group Substances* A number of blood group substances in the stroma of human red blood cells are known, resulting from the allelic series, A<sub>1</sub>, A<sub>2</sub>, B and O, the allelic series M, N<sub>1</sub> and N<sub>2</sub>, and the Rh group of substances which may be an allelic series, or at least closely related, i.e., due to genes closely linked on the same chromosome.<sup>37</sup> According to Landsteiner,<sup>38</sup> the little that is known of their chemistry suggests that they may represent a new type of biologic compound. The group substances that have been studied have a high content of acetyl glucosamine, and galactose and contain amino acids in peptide linkage. The proportion of hydroxy amino acids, threonine and hydroxyproline in both group O and group A substances is higher in concentration than is found in most proteins. From the

stroma of erythrocytes the group substances may be extracted to a certain extent with alcohol but not with water, indicating that they may be present in some lipid combination in the stroma. After extraction from the stroma they appear to be water soluble.

The work of Kabat et al.<sup>39</sup> has indicated that the blood group A substances prepared from human sources such as saliva, stomach and amniotic fluid were similar in content of nitrogen, glucosamine, reducing sugar, and acetyl values. The substances A<sub>1</sub> and A<sub>2</sub> differed in optical rotation. All of the human A substance were levorotatory while the A substance from hog stomach was dextrorotatory. Landsteiner and Harte<sup>40</sup> considered that about one-fourth of the total N represented amino acid nitrogen. Morgan,<sup>41</sup> using paper chromatography, qualitatively identified at least fifteen different amino acids in the acid hydrolyzate of A substance.

The group O substance, isolated from cystic fluid by Morgan and Waddell,<sup>42</sup> contained about 43 per cent of the N as  $\alpha$  amino acid nitrogen. Some of these amino acids were suggested to be joined by glycosidic linkage to the first carbon atom of hexosamine, a linkage which is extremely susceptible to the action of dilute alkali. Studies of group A and O substances, obtained from the stomach linings of hogs, have revealed no chemical differences, except in their immunological properties. They are similar in viscosity and electrophoretic mobility at pH 7.4, both contain l-fucose, d-galactose and d-glucosamine and both also have the same nitrogen, reducing sugar, glucosamine and acetyl content.<sup>43</sup>

### III. STRUCTURE OF HEMOGLOBIN AND THE FUNCTION OF SOME OF ITS PARTS

*Hemoglobin* is the major constituent of the mature red cell, making up about 95 per cent of the dry weight of the cell. Here we have a remarkable achievement in differentiation and specialization. Not only is the hemoglobin specialized for the transport of oxygen, but it also functions indirectly to bring about the transport of CO<sub>2</sub>, without changing the pH of the blood stream. We shall now proceed to an examination of the anatomy of the hemoglobin molecule and consider some of the functions of its parts.

Hemoglobin is a protein molecule of molecular weight 68,000 (fig. 2). It is made up of a large colorless protein portion called globin. On the surface of this globin are present four small prosthetic groups of heme molecules. Two hemes are represented on the proximal surface and two other hemes are on the distal surface, both sets of hemes lying in parallel planes. These four heme molecules are colored and impart the red color to the hemoglobin molecule. The heme molecule is a metal complex consisting of an iron atom in the center of a porphyrin structure. The naturally occurring heme, which is ubiquitous in protoplasm and is present as a prosthetic group in various oxygen transporting proteins, and in a number of enzymes such as catalase, peroxidase, etc., is iron protoporphyrin 9 (fig. 3).

*Protoporphyrin 9*. This molecule consists essentially of four small pyrrole rings attached to each other through —CH methene bridges. This makes an innermost sixteen-membered ring of carbon and nitrogen atoms held together by a conjugated chain of alternating single and double bonds. Such a structure is called a resonating structure and contains  $\pi$  electrons, which appear to have free mobility along the

conjugated chain. The individual pyrrole rings also enter into this resonance, and the inner large ring and smaller pyrrole rings may be considered to be, to a limited extent, pathways for the conduction of the mobile  $\pi$  electrons. All the atoms partaking in this resonating structure lie in the same plane so that the porphyrin molecule is a flat one. The entire structure is greatly stabilized to heat and to strong acids. In addition to the stabilizing effect of the resonance on the porphyrin, the stability of the pyrrole rings is also enhanced by the presence of side chains.

FIG. 2.—INTERPRETATION OF STRUCTURE OF HORSE HEMOGLOBIN

There are four hemes per globin molecule, two hemes are located on the proximal surface with their planes perpendicular to the upper two polypeptide layers. The other two hemes are located on the distal surface perpendicular to the lower two polypeptide layers.

In this particular porphyrin, i.e., protoporphyrin, there are three kinds of side chains, namely four methyl groups, two vinyl groups, and two propionic acid groups. Of the fifteen possible arrangements of the side chains around the circumference of the porphyrin, the natural isomer of protoporphyrin, designated as isomer #9, has the following arrangement, namely methyl, vinyl, methyl, vinyl, methyl, propionic acid, propionic acid, methyl.

Using tracer methods, Shemin and Rittenberg<sup>44</sup> have found that the nitrogens of the four pyrrole rings are derived from the N of the amino acid glycine. The  $\alpha$  C of the glycine forms an  $\alpha$  C of the pyrrole ring, but the carboxyl of glycine is

split off during some step of the synthesis.<sup>46-48</sup> Experiments with labeled acetic acid suggest that both C atoms are utilized, possibly for the synthesis of the side chains, but it is not yet clear whether acetic acid is directly incorporated.<sup>44</sup>

Evidence derived from studies of porphyrin metabolism in *Hemophilus influenzae*<sup>47</sup> suggests that the protoporphyrin ring is not formed piecemeal around an iron atom, but rather it is necessary to assume that the protoporphyrin ring is first completely formed and iron is inserted thereafter. The vinyl groups of the protoporphyrin ring appear to be essential if the organism is to be capable of inserting the iron into the protoporphyrin ring. It is not yet known what enzyme system is concerned with the process of iron insertion. Evidence also suggests that the two propionic acid side chains function in the ionized form to orient the heme and help attach the heme to the globin. The two negatively charged carboxyl groups are postulated to attach to two positively charged groups of the globin with a pK in the neighborhood of 12, possibly guanidino groups of arginine.

FIG. 3.—Fe PROTOPORPHYRIN

The concentration of protoporphyrin in the mature human red cells is very low being about 2.6–3.8  $\gamma$  per 100 cc. of red cells.<sup>48</sup> The red fluorescent pigment in red cells, first noted by Van den Bergh in 1928, was isolated and identified as protoporphyrin 9 by Grotepass<sup>49</sup> in 1937. As with all intermediates the content of free protoporphyrin depends on the rate of its synthesis from precursors and the rate of its removal by its combination with iron to form heme. In the developing and maturing red cell, the rise and decline in the rate of protoporphyrin synthesis appears to follow the rise and decline in the rate of hemoglobin synthesis. For example, erythroblasts contain no protoporphyrin, normoblasts are richest in it, reticulocytes contain less and the mature erythrocyte still less. In general, protoporphyrin is found to be high in cases of iron deficiency anemia (10–20 times the normal), in anemia of chronic infections (where iron does not appear to be mobilized) and in lead poisoning.<sup>48</sup> Low values have been reported in pyridoxine deficiency. London,<sup>50</sup> using labeled glycine, has recently shown that reticulocytes

induced by phenylhydrazine in the rabbit can synthesize heme in vivo. Watson, Grinstein and Hawkinson<sup>51</sup> had reported that by incubating blood in vitro for 24-48 hours, an increase in protoporphyrin was noted. In the light of the tracer experiments, this increase might now be interpreted as an indication of protoporphyrin synthesis in the incubated cells.

*Iron Protoporphyrin* <sup>9</sup> The space in the center of the porphyrin is of the correct size to accommodate an iron atom. Larger and smaller atoms can be held but they are in general (with the exception of copper) held less firmly than is iron. The iron is hexavalent,  $Fe^{2+}$ , it can bind six atoms or atom groups. In the plane of the flat porphyrin ring it links up with four N atoms. It may now bind one atom or atom group below the plane of the ring and one above the plane of the ring (fig. 2). When the bond of the iron below the plane of the ring is attached to a certain group in the globin molecule, then the remaining coordination valence above the plane of the ring can attach reversibly to oxygen and can act as an oxygen transporter.

In the bone marrow, as well as in the liver and spleen, a storage form of iron is present, called ferritin<sup>52</sup>. This is a protein which contains over 20 per cent by dry weight of iron. The protein has a molecular weight of 460,000. Attached to the surface of the protein are clusters or micelles of ferric hydroxide molecules of a special kind. The iron of this storage protein is postulated to be made available by reducing substances in the tissues which reduce the ferric iron to the ferrous form. The ferrous iron is sufficiently soluble so that it might diffuse short distances in the bone marrow, perhaps into immature red cells where hemoglobin synthesis was taking place. The protein component of ferritin is found to be depleted in response to rapid blood formation suggesting that the amino acids of ferritin might be utilized in the synthesis of proteins like globin.

The synthesis of heme may be followed by means of tracer labeled glycine.<sup>44</sup> It has been found that there is no turnover in the hemoglobin of the mature red cell. The average life span of heme and hemoglobin is the same as that of the red cell, about 120 days. By incubating duck erythrocytes with labeled glycine in vitro at 37°C, Shemin<sup>14</sup> has been able to demonstrate the incorporation of  $N_{15}$  into the hemoglobin heme. Immature cells obtained by frequent bleedings synthesize to a greater extent. London et al.<sup>60-62</sup> have found that rabbit reticulocytes in vitro can also incorporate labeled glycine into heme and that the whole blood of sickle cell anemia subjects can synthesize heme in vitro, in sickle-cell-trait without anemia no synthesis was observed.

No method has been developed to determine the free heme of the red cell and no information is available as to the relative levels of heme and globin in the developing red cells. After feeding labeled glycine, London<sup>60</sup> found a rapid early and unexpectedly high rate of excretion of labeled stercobilin. One explanation that has been suggested for this result is that heme synthesis takes place in the young red cells in great excess over that of globin synthesis and that the excess heme which is not bound to the globin is broken down and excreted in the bile.

*The Amino Acids of Globin and Certain of their Functions* The protein globin has a molecular weight of 66,000. It is a more basic protein than most of the tissue

proteins. The isoelectric point is 6.8 for ferrous hemoglobin and 6.5 for oxyhemoglobin (54). The amino acid composition of globin is not completely known. A study of the amino acids of hemoglobin of a number of mammalian species reveals that the globins are rather similar in the relative amounts of several of the different amino acids contained in them. For example, the approximate molecular ratios of tryptophane:tyrosine:arginine:histidine:lysine are 1:3:3:8:10, respectively, or, in terms of the number of molecules of these amino acids per globin, approximately

TABLE 1—*Amino Acid Analysis of Hemoglobin in per cent*  
(Modified from Cartwright<sup>55, 56, 57, 58</sup>)

Amino acid	Horse	Man	Number of amino acid residues per horse globin molecule
Leucine	15.1	17.2	76
Isoleucine	0.11	0	8
Histidine	7.7	8.0	33
Arginine	3.7	4.2	14
Lysine	8.6	—	41
Valine	9.8	10.1	64
Tryptophane	1.1	—	4
Phenylalanine	6.8	—	27
Methionine	0.75	1.2	3
Cystine	0.85	1.2	2
Threonine	6.8	6.8	38
Tyrosine	3.0	—	12
Alanine	8.9	9.9	61
Glycine	5.6	—	50
Serine	5.3	—	33
Proline	2.0	—	11
Hydroxyproline	0.0	—	0
Aspartic	10.3	—	51
Glutamic	8.5	—	39
Amide N in % of total N	4.58	—	48
Total S	0.4	0.6	
Total N	16.4	16.6	
Total Fe	0.335	0.335	4

as 4:12:14:33:41. The relative high content of arginine, histidine and lysine residues are in part responsible for the high isoelectric point of globin. Because of this high isoelectric point the affinity for acidic dyes such as eosin is greatly enhanced. Since more data is available on horse hemoglobin, this protein will be considered in an analysis of hemoglobin structure.

Some functions may be postulated for several of the constituent amino acids of globin. Relative to other proteins, globin is one of the richest in histidine content, there being about 33 histidines per globin molecule. The histidines may be postulated to have three functions. The most important function would appear to be that one of the imidazole nitrogens furnishes the seat of attachment for one of the coordination valences of the iron of heme, thus making possible the reversible oxy-

genation of hemoglobin (*vide infra*). The evidence for this iron link is indirect. Four histidine residues would be involved, one for each of the four hemes on the globin. It is further postulated that the second nitrogen of these same imidazole groups would be involved in the change of acidity with change in oxygenation of the hemoglobin. This Bohr effect makes possible the transport of  $\text{CO}_2$  as bicarbonate ion. The third function of histidine in hemoglobin is due to the fact that the histidine residues serve as excellent buffers, since the  $\text{pK}$  of the imidazole nitrogens lies in physiological pH range. Some 29 histidine residues may function in this regard. According to Wyman, between pH 5.5 and 8.8 there are titrated 31 groups in all, most of which probably are in the histidines. This buffering capacity would become important in cases where much lactic acid escaped into the blood stream, as in severe exercise.

The lysine  $\epsilon$ -amino groups and the arginine-guanidino groups make up a total of 55 positively charged groups. Eight of these positively charged groups are postulated to be combined with eight propionic acid side chains of the four hemes. Porter and Sanger<sup>59</sup> have found that the reagent, fluoro dinitrobenzene, determines all of the  $\epsilon$ -amino groups of lysine in the presence or absence of the hemes. This suggests that all the  $\epsilon$ -amino groups are free, that they lie on the surface of the globin, and that the propionic acid groups of heme are most probably attached to the guanidino groups of arginine rather than to the  $\epsilon$ -amino groups of lysine. Including the six positively charged amino groups at the ends of the polypeptide chains this would make a total of 53 free positively charged groups at pH 7, exclusive of the imidazole residues. The ionized carboxyl groups, of glutamic and aspartic acid together, total 43 groups after correction is made for amide nitrogen. In addition there are six carboxyl groups at the ends of polypeptide chains, thus giving a total of 49 negatively charged groups, these probably play an insignificant role in buffering.

Roughton<sup>60</sup> has postulated that some 20-30 per cent of the total  $\text{CO}_2$  is trans-

Since carbamate formation is decreased in oxyhemoglobin as compared with hemoglobin, Roughton has suggested that the attachment of the  $\text{O}_2$  in some way may interfere sterically with the formation of carbamate. Carbamic acids have a  $\text{pK}$  of about 5.8. Only uncharged  $\alpha$  amino groups combine with  $\text{CO}_2$  to form carbamino compounds. In horse globin six free amino groups are present (in the human, 5), namely, the amino groups of valine at the ends of the peptide chains.<sup>59</sup> Such amino groups would have a  $\text{pK}$  around 9 and would be present at body pH in the form of  $\text{R}-\text{NH}_3^+$ . Since  $\text{CO}_2$  combines with the  $\text{R}-\text{NH}_2$  group, it would be necessary to postulate a shift of the valine amino group by some 2 pH units to the acid side to account for significant  $\text{CO}_2$  transport as carbamino compound. Wyman has calculated that transport of 10 per cent of  $\text{CO}_2$  in the respiratory cycle could be due to carbamate.<sup>61</sup> The assumptions and postulates on carbamate have been discussed in detail more recently by Wyman.<sup>61</sup>

It is interesting to note a possible structural function of another amino acid, proline. Pauling<sup>67</sup> has suggested that proline, because of its geometry might serve as a 90-degree bend or elbow-joint in the polypeptide chain.

*Hemoglobin Structure* Intensive x-ray analyses of horse ferric hemoglobin by Boyes-Watson, Davidson and Perutz<sup>68</sup> have led to a clearer concept of the structure of the hemoglobin molecule. It has a molecular weight of 68,000 and its dimensions, calculated on the basis of a cylindrical structure, with convex ends, are  $57 \times 57 \text{ \AA}$  by  $34 \text{ \AA}$  high (fig. 2.) The assumption of a cylindrical structure for the volume of the globin is a mathematically convenient one. It is not a unique solution for the data, however, and should be considered only as an approximation to the actual shape.

One interpretation of the globin structure is that in the  $34 \text{ \AA}$  dimension the globin consists of four parallel monolayers of polypeptides, each about  $8\frac{1}{2} \text{ \AA}$  thick. This  $8\frac{1}{2} \text{ \AA}$  dimension corresponds to the average thickness of a monolayer of a protein, including its side chains, when completely spread out on a Langmuir trough. The polypeptide layers contain polypeptide chains or rods running the length of the molecule along the x direction.<sup>69</sup> The polypeptide chain is not fully extended. Along its length there appear to be regularly spaced small folds some  $5 \text{ \AA}$  apart, the folds being equivalent to a distance of two amino acid residues along the chain. This kind of fold is similar to that described by Astbury as the contracted or alpha-keratin type. According to this interpretation the wrinkled polypeptide chain running along the x direction would be a roughly cylindrical elongated rod with an average diameter of  $10.5 \text{ \AA}$ . Along the y direction, i.e., in a polypeptide layer of the globin, one could fit about 5 such rods, or the 4 polypeptide layers could contain a total of 20 such rods. The studies of Porter and Sanger<sup>70</sup> reveal only six free amino groups suggesting that there are only six polypeptide chains in horse globin. However, as yet it is not possible to rule out cyclic chains, nor chains branching off from some carboxyl groups of glutamic or aspartic acids.

It can be determined from optic dichroism that the four hemes, which are flat or planar molecules, lie parallel to each other in the protein crystal. Because the hemes can be oxidized to the ferric state with relatively large molecules such as ferricyanide, and because the hemes may be removed from the globin in a somewhat reversible manner,<sup>71</sup> it is reasonable to consider that the hemes are on the surface of the globin. In addition, the stability of the heme globin combination makes it probable that Van der Waals forces occur between the resonating ring and the globin surface and it is reasonable to assume the arrangement of heme and globin to be such that the plane of the flat heme molecule lies on an area of the globin surface which is planar. From x-ray data, it is known that the plane of the heme is perpendicular to the x axis of the globin. The hemes, therefore, lie perpendicular to the ends of the polypeptide rods. Studies of the protein in solutions of high urea or salt concentration suggest that the protein is split into two identical halves, each half being made up of two polypeptide layers. Since a plane of symmetry is present in the hemoglobin molecule, each half of the molecule must be structurally and chemically identical.<sup>72</sup> These facts suggest that a pair of hemes belong to the upper half of the molecule and a pair of hemes belong to

the lower half Wyman<sup>54</sup> interprets the hyperbolic oxygenation curve of hemoglobin as indicating that there is a strong interaction between hemes belonging to the same pair and little interaction between hemes belonging to different pairs. On this basis, the hemes belonging to the same pair are placed close together, one pair of hemes being represented on the proximal surface of the molecule lying perpendicular to the two upper polypeptide layers (fig. 2), the other pair of hemes being on the distal surface of the molecule and lying perpendicular to the two lower polypeptide layers. It is interesting to consider that the attachment of the hemes to these rods of polypeptides binds the rods together and stabilizes an otherwise highly unstable protein molecule.

The density of the protein indicates that the polypeptide chains in the layers, and the layers themselves, are packed very closely. The water associated with the protein is probably present as one or perhaps two monolayers surrounding the protein molecule.

*Effects of Interaction of Heme-iron and Globin* The iron atom in Fe protoporphyrin 9, 1c, heme, has the ability to bind six groups, that is, it has a coordination valence of 6. It binds the four pyrrole nitrogens in the plane of the ring and is able to bind a group below the plane of the ring and a group above the plane of the ring. In hemoglobin, it is postulated<sup>55, 54</sup> that the iron is attached to a nitrogen of the imidazole group of histidine. When this attachment occurs, and when the iron is in the ferrous, that is, the reduced state, then the molecule of O<sub>2</sub> can be attached reversibly at the sixth coordination place of the iron. Wyman has shown that from the effect of temperature on the titration curve of oxyhemoglobin a heat of dissociation of 6,200 calories per mol can be calculated, a value expected for ionizable groups like the nitrogen of imidazole. The effect of change of pH on the heat of oxygenation also gives a value compatible with such compounds. The effect of pH and temperature on the form of the O<sub>2</sub> equilibrium curve is interpreted by Wyman as evidence that all the hemes are attached to identical local configurations on the globin.

The linkage of the iron of the heme to the protein is an all-important one. It endows the complex of heme and globin with the peculiar property of permitting the sixth coordination link to be reversibly held by an oxygen molecule. Ferrous heme, free in solution, is rapidly oxidized by O<sub>2</sub> to the state of ferric heme. This oxidation does not occur when the heme is attached to globin. The binding of the ferrous iron of heme to globin permits the addition of O<sub>2</sub> but the O<sub>2</sub> here is stabilized. The O<sub>2</sub> cannot act as an oxidizing agent, that is, it cannot accept an electron. If one measures ferrous hemoglobin magnetically it is found that the iron has four unpaired electrons in its 3d shell. The O<sub>2</sub> molecule is actually a biradical and so possesses two unpaired electrons. Now when O<sub>2</sub> unites with ferrous hemoglobin, a profound change in the magnetic susceptibility is observed.<sup>56</sup> The resulting compound, oxyhemoglobin, is diamagnetic. This means that all the unpaired electrons of the iron and of the O<sub>2</sub> have paired. And it is perhaps this change which is significant in preventing the ferrous globin from being oxidized to the ferric state (i.e., to methemoglobin).

Combination of hemoglobin with oxygen is a much more rapid process than is

its dissociation. The rapidity with which oxygen may be combined or removed is brought out by the following data and calculations. The velocity of combination of oxygen with hemoglobin to form oxyhemoglobin and the dissociation of oxyhemoglobin to form hemoglobin and oxygen have been measured in sheep blood at 20 C by Hartridge and Roughton.<sup>67</sup> Considering that each heme of hemoglobin is independent of other hemes, the first order velocity constant for the dissociation of the heme-O<sub>2</sub> complex into heme + O<sub>2</sub> is 20 per second, that is, it would require 0.035 seconds for half of the oxyhemoglobin to dissociate. For the combination of the heme of hemoglobin with O<sub>2</sub>, the second order velocity constant is 3,000 per second per millimole liter, that is, assuming 9.4 as the millimolar concentration of heme in the blood and an equimillimolar concentration of O<sub>2</sub>, then 50 per cent of hemoglobin would be combined with O<sub>2</sub> in  $3.5 \times 10^{-3}$  seconds. From this we see that the velocity of combination of O<sub>2</sub> with heme to the 50 per cent point is 1000 times as great as the velocity of dissociation of oxyhemoglobin to the 50 per cent point.

It is interesting to compare these figures of oxygenation with those in which CO combines with hemoglobin. For the dissociation of carbon monoxide hemoglobin the first order velocity constant is 0.01 per second. For its formation, the second order velocity constant is 250 per second per millimole liter. The CO complex therefore is formed at only one-tenth the velocity of formation of the O complex. For a dissociation of 50 per cent of carbon monoxide hemoglobin, 69 seconds would be required. For the formation of 50 per cent of carbon monoxide hemoglobin, assuming the millimolar concentration of heme in the blood and an equimillimolar concentration of CO,  $4.2 \times 10^{-4}$  seconds would be required. Thus the velocity of combination of CO to the 50 per cent point would be 160,000 times as great as its dissociation to the 50 per cent point.

The linkage of the iron of heme to the globin is important in another respect, namely, in the so-called isohydric transport of CO<sub>2</sub> in the blood stream. From the data of Wyman it appears that in oxyhemoglobin a group with a pK of 6.8 is present, and that when O<sub>2</sub> is removed the pK of this group changes to 7.8. In other words, at the pH of the blood, when O<sub>2</sub> adds to hemoglobin a proton (H<sup>+</sup>) tends to dissociate off. When O<sub>2</sub> comes off the oxyhemoglobin, a proton tends to go back on (fig. 4). This effect, of hemoglobin becoming more acidic on oxygenation, is called the Bohr effect.

The group which undergoes this change on oxygenation has been suggested by Coryell and Pauling<sup>68</sup> and by Wyman<sup>64</sup> to be the nitrogen of the heme linked imidazole group. Pictured in more detail (fig. 4) one might consider that the resonating ring of the porphyrin is coupled through the iron to the resonating imidazole ring. Then the addition of O<sub>2</sub> to hemoglobin would cause a slight displacement of the resonating electrons toward the O<sub>2</sub>, this would make the imidazole nitrogen a little more positive, thus decreasing the binding of this nitrogen for its H<sup>+</sup>, and the H<sup>+</sup> would tend to dissociate off more readily (i.e., the pH of the nitrogen would shift from 7.8 to 6.8). This effect is as though O<sub>2</sub> itself were an acid and enabled the blood to carry 0.7 mol of H<sub>2</sub>CO<sub>3</sub> as bicarbonate ion per mol

of  $O_2$  exchanged, or some 60 per cent of the total  $CO_2$ , without any pH alteration<sup>66</sup>

In figure 4 some of the events of  $CO_2$  transport in connection with hemoglobin have been summarized schematically. Here a heme group is shown sitting on the globin surface, the iron coordinating with the four pyrrole ring nitrogens, a fifth coordination link being connected with a nitrogen of an imidazole ring of histidine in the peptide chain of the globin. The sixth coordination link now may combine with  $O_2$  reversibly

FIG. 4—SCHEME REPRESENTING THE EFFECT OF OXYGENATION OF HEMOGLOBIN ON THE TRANSPORT OF  $CO_2$  AS BICARBONATE ION

The pathway of  $CO_2$  and  $O_2$  molecules in the blood stream is shown on the diagram. When blood comes to the lungs (fig. 4-A),  $O_2$  adds to the 6th coordination link, a rearrangement of electrons occurs, bringing about the dissociation of a proton,  $H^+$ , from the imidazole-N. The proton very rapidly combines with  $HCO_3^-$  to form  $H_2CO_3$  (ionization reactions being extremely rapid). Conversion of  $H_2CO_3$  to  $H_2O$  and  $CO_2$ , i.e., dehydration-hydration reaction, is relatively slow. The attainment of equilibrium of this reaction is catalyzed by the zinc protein enzyme, carbonic anhydrase. The excess  $CO_2$  produced diffuses into the plasma and out through the lungs.

The blood then flows toward the tissues (fig. 4-B). Here the  $CO_2$  moves into the red cells to be hydrated to  $H_2CO_3$  by way of the carbonic anhydrase enzyme. The  $H_2CO_3$  dissociates to  $H^+$  and  $HCO_3^-$ . At the same time that  $O_2$  comes off, the ferrous hemoglobin now accepts the  $H^+$ . In connection with all of these events

there occur shifts in  $\text{Cl}^-$ ,  $\text{HCO}_3^-$  and  $\text{H}_2\text{O}$ , to take care of Donnan ion effects and osmotic changes,<sup>68</sup> but these cannot be considered here

According to the hypothesis of the heme-linked imidazole group, one might expect all  $\text{O}_2$ -transporting heme proteins to show a significant Bohr effect. This Bohr effect has been observed for the circulating mammalian and most invertebrate hemoglobins.\* However, a number of exceptions have been noted. The Bohr effect for muscle hemoglobin is so small that it may be within experimental error, and no Bohr effect has been observed in *Gastrophilus*<sup>69</sup> or *Urechis* hemoglobins. Whether a modified imidazole must be postulated in these latter cases, or some other group or effect, is not known. Another objection that has been raised to the heme-linked imidazole hypothesis is that the addition of imidazole compounds directly to heme gives no evidence for a stable oxygenation complex, but the difficulty may be that the existence of such a complex might require a stable spatial molecular arrangement.

*Other Effects of Interaction of Amino Acids Adjacent to the Hemes* When the sharp  $\alpha$  bands of  $\text{O}_2$  and CO hemoglobins are measured with a Hartridge reversion spectroscopy for various vertebrate and invertebrate species, slight differences are noted in the positions of the bands. The position of the bands for a particular species is highly constant and indeed is a delicate test to support the idea of the invariable character of a specific protein in a given species. Among various species the difference between the wave length of the  $\alpha$  band of  $\text{O}_2$  and CO hemoglobin, called the span, may vary by as much as  $\pm 40 \text{ \AA}$ .<sup>70</sup> These displacements of band positions are considered to be due to differences in the kinds of amino acid groups adjacent to the heme and their spatial distribution around the heme. Another expression of differences in behaviour of different hemoglobins is the relative affinity of  $\text{O}_2$  as compared to CO for the hemoglobin of a particular species.<sup>71</sup>

If the position of the amino acids surrounding the heme may affect the positions of the absorption bands, one might consider that the change on oxygenation of hemoglobin might also affect some of these neighboring amino acids. For example, on oxygenation of horse hemoglobin there appears to be evidence for a group changing from  $\text{pK } 5.25$  to  $\text{pK } 5.75$ .<sup>54</sup> This group has been postulated to be an imidazole group whose proximity to the heme, rather than direct linkage, might affect its ionization. One might also explain some of the changes in carbamate concentration as affected by oxygenation, by postulating valine amino groups at the ends of the peptide chains to be located adjacent to the hemes. Eventually too, the variation in affinity of various hemoglobins for  $\text{O}_2$  with changes in  $\text{O}_2$  tension, may find their explanation on the basis of structural effects of amino acids of globin adjacent to the heme.

*The Form of Hemoglobin in the Erythrocyte* The erythrocyte contains some 30 per cent, by wet weight, of hemoglobin. This concentration of hemoglobin is so high that one might expect to observe properties of hemoglobin which deviate from hemoglobin in dilute solution. Ponder<sup>18</sup> has calculated that if hemoglobin mole

\* As noted by Redfield<sup>127</sup> there is a considerable variation in the degree of the Bohr effect among various species.

cules were arranged in hexagonal packing there would only be enough water to form a layer of 10 Å around each hemoglobin. On the average, the distance apart between two hemoglobin molecules at closest approach in the red cell, as determined by x-ray diffraction, is of the order of magnitude of two water molecules.

When the oxyhemoglobin formed from ferrous hemoglobin is plotted against the tension of  $O_2$ , it is found that the resulting  $O_2$  affinity curve is sigmoid in shape.\* For muscle hemoglobin containing one heme per molecule the curve is a rectangular hyperbola. It has therefore been postulated that the sigmoid curve of red cell hemoglobin is due to interactions of the hemes. In horse hemoglobin the hemes appear to lie on the globin in pairs (fig. 2). Wyman believes there is strong interaction between hemes of the same pair such as to make the first  $O_2$  attach to hemoglobin less readily and the next  $O_2$  attach more readily. In support of this idea of the interaction of hemes of the same pair on each other, is suggested the fact that in strong urea solutions horse hemoglobin splits into two equal halves each containing a pair of hemes, and the sigmoid shape of the  $O_2$  equilibrium curve of these halves of molecules is largely maintained. In addition to this interaction, there appears to be an interaction between hemes of different pairs, probably hemes belonging to different ferrous hemoglobin molecules, (rather than oxyhemoglobin molecules), and this interaction may be influenced in part by dilution. It is not yet clear, however, to what extent the sigmoid curve is influenced by close approach of hemes of different molecules, by splitting of the molecules on dilution, by effects of various salts, nor is it clear how the hemes interact to affect the  $O_2$  affinity. Human hemoglobin is said to be only slightly dissociated into smaller molecules on dilution and yet shows a significant change in the  $O_2$  tension curve.

Hill and Wolvekamp<sup>72</sup> report the following interesting experiment in connection with the sigmoid curve. They found that by diluting the concentrated human hemoglobin of the red cells five times, the  $O_2$  tension for half saturation of the hemoglobin with  $O_2$  dropped from 9.8 mm  $O_2$  down to 3.1 mm  $O_2$ , and was not decreased further even on greater dilution. Seeking for an explanation of this behavior these authors discovered that a substance could be obtained by dialyzing horse corpuscles which, when added to a dilute solution of hemoglobin, shifted the  $O_2$  tension curve towards that found for more concentrated hemoglobin solutions. The substance in the dialysate was destroyed by boiling and became inactive after four days in the cold. Perhaps it is this substance which may account in part for the  $O_2$  tension curve of the red cell.

The unexpectedly low quantum yields when horse CO-hemoglobin is dissociated by light suggest the possibility of some kind of interaction in the hemoglobin molecule as a unit. Warburg<sup>129</sup> reports that only one CO is split off for 4 light quanta absorbed, perhaps indicating that the binding of one of the four CO-hemes is looser than the others. On splitting hemoglobin into two equal halves (in 2.6 M NaCl at pH 7.6), one CO is split off for 2 light quanta absorbed. In muscle

\* This is true in general for mammalian erythrocyte hemoglobins. However in the blood of fishes the sigmoid-shaped curve may be scarcely observed or may be lacking. The peculiar curves for duck and pigeon hemoglobins where a slow proportionate increase of oxyhemoglobin occurs with increasing  $O_2$  tension have yet to be explained.<sup>127</sup>

CO-hemoglobin, where there is only one heme per protein molecule of molecular weight 16,500, one CO is split off for every light quantum absorbed

Another problem in connection with the very high concentration of hemoglobin in the red cells is, why does not the hemoglobin normally crystallize out within the cell? For example, when guinea pig red cells are laked with water, crystals of oxyhemoglobin appear almost immediately. These crystals are formed in a dilute solution as compared to the concentrated solution in the red cell where crystals are not observed. Not only would crystallization in the red cell be harmful by causing mechanical injury, but crystallization would also be deleterious since it has been found that oxyhemoglobin in the crystalline state holds on to its  $O_2$  so tenaciously that it could not serve for reversible  $O_2$  transport.<sup>73</sup> In sickle cells, the formation of the sickle occurs when the hemoglobin is deprived of  $O_2$ . It is interesting that human ferrous hemoglobin, unlike guinea pig hemoglobin is said to be less soluble than oxyhemoglobin, suggesting that the phenomenon of sickling might be related to incipient crystallization of the ferrous hemoglobin.

*Fetal Hemoglobin* Recent evidence has shown that a fetal hemoglobin is produced whose properties differ from those of normal adult hemoglobin. It was Barcroft who first called attention to the fact that differences existed between fetal and adult hemoglobins. Brinkman and Jonxis<sup>74</sup> showed that below the age of three in humans there was a hemoglobin which was labile to alkali, and that after this period the hemoglobin changed over to a form that was alkali stable. Wyman et al.<sup>75</sup> later found that the CO hemoglobin of fetal cow blood was more than six times as soluble in strong phosphate buffer at pH 6.8 than was adult cow blood. Vickery<sup>76</sup> analyzed these hemoglobins and found that fetal bovine hemoglobin contained  $6.43 \pm 0.04$  per cent histidine whereas adult bovine hemoglobin contained  $6.81 \pm 0.05$  per cent histidine, indicating that the change is a quantitative one and not merely a change in the spatial arrangement. In addition, Hill and Wolvekamp<sup>77</sup> have shown that fetal hemoglobin, like muscle hemoglobin, has a higher affinity for  $O_2$  than has adult hemoglobin, that is,  $O_2$  is removed from these hemoglobins at lower oxygen tensions than from adult hemoglobin. The conclusion that there are two distinct substances is thus supported. A reasonable interpretation is that the fetal hemoglobin may be produced in organs other than the bone marrow, e.g., such as the liver, and that only the adult hemoglobin is produced by the bone marrow.

#### IV PROTEINS OF THE RED BLOOD CELL

Besides the hemoglobin, the stroma proteins, and the protein enzymes of the glycolytic system (which will be considered in another section), a number of other proteins have been found in the erythrocyte.

*Metal Containing Proteins* There is only one iron containing protein in the red cell besides hemoglobin that is known, i.e., catalase. The cytochromes and cytochrome oxidase appear to be lacking. In consequence, the  $O_2$  utilization of the red cells is very small.

*Catalase* content of erythrocytes appears to be relatively high. It appears to have properties probably identical with the catalase of liver. The protein has a molecular

weight of 325,000 and contains four hemes per protein molecule.<sup>77</sup> One obvious function of catalase is the protective one, i.e., of destroying  $\text{H}_2\text{O}_2$  which might be produced in the red cells. The catalase may also have a peroxidase activity of low order and, in the presence of very small amounts of  $\text{H}_2\text{O}_2$ , it may oxidize the lower alcohols to aldehydes, the aldehydes to acids, and formic acid to  $\text{CO}_2 + \text{H}_2\text{O}$ .<sup>78</sup>

*Carbonic anhydrase* is a zinc protein which, according to Scott<sup>79</sup> contains 0.2 per cent of zinc. It has a molecular weight of 30,000 and an isoelectric point of 5.3. It was first postulated to exist by Henriques who calculated that the spontaneous decomposition of  $\text{H}_2\text{CO}_3$  is too slow a reaction to liberate  $\text{CO}_2$  from the blood stream. Meldrum and Roughton demonstrated its existence in 1932, and it was crystallized from the red cells by Keilin and Mann<sup>80</sup> in 1940. The enzyme is a hydrolytic one catalyzing the reaction  $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$ . There is sufficient carbonic anhydrase in the red cells to accelerate this reaction about 1,500 times at 38°C and this is about ten times the required acceleration. All the zinc in the red cells is accounted for as a component of carbonic anhydrase. The enzyme is inhibited by low concentrations of cyanide and sulfanilamide.

*Hemocuprein* is a cupric-containing protein. It is bluish in color, contains 0.34 per cent Cu, has a molecular weight of 35,000 with two copper atoms per protein molecule. It was isolated by Mann and Keilin in 1938<sup>81</sup> from red cells. Its function is not known. The copper can be reduced but cannot be oxidized back to its original color. The anemia of copper deficiency, like that of iron deficiency, is microcytic and hypochromic. The possibility that a copper compound catalyzes the formation of cytochrome oxidase or is a component of the cytochrome oxidase system has not yet been eliminated.<sup>82</sup>

*Phosphomonoesterase*. There appear to be both an  $\alpha$  and a  $\beta$  glycerophosphatase in human red cells according to Paget and Vitter.<sup>83</sup>

*Choline Esterase*. Human red cells contain a potent true choline esterase, i.e., specifically inhibited by  $\beta, \beta'$  dichlorodiethyl-N-methylamine or by caffeine.<sup>84</sup> The choline esterase of human erythrocytes and of brain are very similar, if not identical, but both differ considerably from the choline esterase of human plasma. According to Mentha et al.,<sup>85</sup> the esterase can be extracted from chilled red cells at pH 8.3 with little hemolysis. This would suggest that the choline esterase may be at or near the cell surface.

Stern and coworkers<sup>86</sup> have separated two other protein components from the erythrocyte by electrophoresis, protein a probably being related to stomatin, protein b not being identified as yet. In the course of preparation of stomatin, a globulin was also found in the supernatant fluid. Elinin and the carbohydrate-poor albumin anti-sphering protein have been discussed in a previous section.

## V WATER SOLUBLE CONSTITUENTS OTHER THAN PROTEINS

All of the glutathione (GSH) of the blood is confined to the red cells where it may undergo rapid oxidation and reduction. It is suggested that together with ascorbic acid, it may play a minor role in the reduction of ferric hemoglobin to ferrous hemoglobin. Thionine, the betaine of thiol histidine, is also confined to

the red cells Porter and Franke<sup>88</sup> consider that this substance may all have been derived from the food Christensen and Lynch<sup>89</sup> believe that the concentrations of  $\alpha$  amino acids and peptide compounds (exclusive of GSH) are rather evenly distributed between the cells and the plasma

TABLE 2.—Concentration of a Number of Substances Found in Human Erythrocytes

Compounds	Concentration in mg./100 cc. red cells	Reference No.
Urea		
Creatine	14	87
Creatinine	3.1	87
Amino acids	0.7	87
Peptides (not GSH)	30	89
Glutathione	13	89
Thionine (ergothioneine)	70	87
Glucose	15	88
Total reducing substances calculated as glucose	74	15
	114	15
ATP + ADP		
DPN	50	93
TPN	10	92
Flavine dinucleotide	1.2	92
	0.075	98
Total NPN		
Nucleotide N	44	87
Amino acid N	13	87
	7.4	87
Inorganic P	2	104
Organic acid soluble P	55	104
ATP P	13.5	104
2,3 Diphosphoglycerate P	28	104
Hexose mono+ diphosphate P	15	104
Neutral S	6	106
Inorganic sulfate S	0.04	106
Ethereal sulfate-S	0.04	106
Na <sup>+</sup>	45	15
K <sup>+</sup>	420	15
Mg <sup>++</sup>	3.0	15
HCO <sub>3</sub> <sup>-</sup>	100	15
Cl <sup>-</sup>	180	15

The adenine nucleotides average about 65 mg./100 cc. of red cells, consisting mostly of adenosine triphosphate (A T P), adenosine diphosphate (A D P) and diphosphopyridine adenine dinucleotide (DPN) or coenzyme I. Smaller amounts of a triphosphopyridine adenine dinucleotide (TPN) or coenzyme II, and still smaller amounts of flavine adenine dinucleotide are also present.

In human red cells under certain conditions the ribose of adenylic acid appears

to be converted to triose phosphate, suggesting that ribose is split into a triose and a two-carbon compound.<sup>90</sup> Racker<sup>91</sup> has recently purified an enzyme from bacterial extracts which also converts ribose 5- $\text{PO}_4$  to triose phosphate.

Approximately 90 per cent of the total blood nicotinic acid is in the corpuscles, and all of the nicotinic coenzymes. The coenzymes are rapidly destroyed when the red cell undergoes hemolysis,<sup>92</sup> indicating that in the intact red cell the coenzymes are probably being broken down and built up at an appreciable rate. Handler and Kohn<sup>93</sup> found that DPN was hydrolyzed at the link between the nicotinamide and the ribose and that this hydrolysis was inhibited by nicotinamide but not by nicotinic acid. Nicotinamide, however, cannot be used directly for DPN synthesis, although nicotinic acid itself is used directly for this synthesis in the red cell. Both nicotinic acid and its amide are equally permeable to the red cell. In vivo, feeding of nicotinamide raised the coenzyme by 25-40 per cent in the circulating cells, feeding of nicotinic acid raised it, however, from 90-300 per cent. (The V factor test for *Hemophilus influenzae* growth<sup>94</sup> was used in their determinations, nicotinamide nucleoside was about one-third as active as DPN.) The enzyme synthesizing DPN is not the same as the hydrolyzing enzyme. Gutman et al.<sup>95</sup> showed that in hemolyzed red cells hexose diphosphate was more readily utilized for the reduction of ferric hemoglobin when nicotinamide was added to suppress DPN hydrolysis. In nicotinic acid deficiency an anemia results leading to degenerate anitosis and premature ripening of the erythrocytes. On feeding nicotinic acid an increase in red cells and in hemoglobin is observed. Evidently the nicotinic coenzymes are necessary even in the immature nucleated erythrocytes.<sup>96, 97</sup>

The red cells can couple ribose to the nicotinic nitrogen to form nucleoside and then phosphorylate with ATP to form nucleotide. Among the specific effects of pyridoxine deficiency leading to a hypochromic anemia in the rat, is the inability to convert tryptophane to nicotinic acid so that the red cells are low in DPN.<sup>98</sup>

No estimates of total alloxazine-containing compounds (the flavines) are available but, compared to the nicotinamide-containing compounds, they appear to be in very low concentration in the red cells. In human red cells, Klein and Kohn<sup>98</sup> found a concentration of flavine adenine dinucleotide of 0.075 mg/100 cc cells. In red cells, the flavine dinucleotide is about 300 times lower on a wet weight basis than in heart or kidney tissue and is 100 times lower than the nicotinamide coenzymes. In the red cell no d-amino acid oxidase activity, for which the flavine dinucleotide is a prosthetic group, was observed.<sup>100</sup> The experiments of Gibson<sup>101</sup> suggest that a diaphorase-like enzyme (which contains the flavine dinucleotide prosthetic group) may be present in the red cell. Electrons then may be transferred rapidly from reduced DPN through diaphorase, through some intermediate carrier, finally to ferric hemoglobin, to reduce the latter to functional ferrous hemoglobin. The addition of riboflavin (alloxazine ribose) to red cells in vivo or in vitro increased the dinucleotide content about 25 per cent after several hours. Alloxazine itself did not increase the dinucleotide content since ribose was unable to couple with it in the red cell.<sup>98</sup>

The phosphate in the red cells is predominantly in the form of organic acid-soluble P. The concentration of inorganic phosphate is here much less than in the

plasma and its value depends on the rate of synthesis and decomposition of the organic esters rather than on the factors governing the Donnan equilibrium. While the rate of penetration of inorganic phosphate into the red cell is slow as compared to other anions,<sup>107</sup> its incorporation into organic phosphate is very rapid.

In most mammalian bloods the concentration of organic acid soluble P varies between 50-100 mg/100 cc red cells with usually one half being 2,3-diphosphoglycerate. This compound differs from the labile, 1,3-diphosphoglycerate, the latter being the normal intermediate in the glycolytic scheme.

Whether the stable diphosphoglycerate is converted to the labile intermediate by way of a mutase, or is brought into the glycolytic scheme by some other means, is not yet known. Rapoport and Guest<sup>102, 105</sup> have suggested that 2,3-diphosphoglycerate might serve in adjusting the anion equivalency in the red cells to changes in the concentration of diffusible electrolytes in some pathological conditions since the concentration of this compound may change rapidly within relatively wide limits.

In reticulocytes, the ATP is 2-3 times higher than in the mature red cell. Nucleoprotein appears also to be present in reticulocytes but not in the mature cells.

It is interesting to note that the concentration of acid soluble P is higher in the nucleated erythrocytes of birds than in mammals, being 90-135 mg/100 cc. red cells with a large proportion of phytic acid-P (50-87 mg/100 cc) and no phosphoglycerate, if the cells of a species contained phytic acid, then it was found that the enzyme phytase was also present in the red cells of this species, otherwise phytase was absent.<sup>104, 108</sup>

The minerals constitute around 0.6 per cent of the wet weight of the cell. In the human red cell there is six times as much  $K^+$  as  $Na^+$ , and  $Cl^-$  is about half that of  $K^+$ .  $Mg^{++}$  is also present in small amounts and is known to serve as a catalyst for some of the steps in the glycolytic scheme. The  $Mg^{++}$  and  $K^+$  contents of reticulocytes are higher than in the mature red cell.

## VI. METABOLIC SYSTEMS OF THE MATURE ERYTHROCYTE

The average life of a circulating erythrocyte is 120 days. Attempts to maintain these cells in vitro at 37°C for even a week show that marked deterioration of these cells takes place. There is liberation of ammonia and exchange of  $K^+$  for  $Na^+$  across the cell membrane soon after the blood is drawn and concomitantly glucose disappears and lactic acid accumulates, ATP decreases, there is also a decrease of the total organic acid-soluble-P with an increase in the concentration of inorganic P, and methemoglobin is gradually formed at a faster rate than it is reduced, the cells turning brownish in color. At the same time the physical structure of the cell is affected, the change being associated with an increase in osmotic fragility (i.e., greater hemolysis in hypotonic solutions compared with the normal), increased thickness, crenation, etc.<sup>107, 108</sup> A loss of the specific polysaccharide antigens *a* and *b* also occurs.<sup>109</sup>

For the maintenance of the integrity of the red cell in vivo, glucose is undoubtedly the main energy source. However, it would appear that other factors of the plasma, continuously being generated by the tissues of the body, must also take

part. The biochemistry of some of these processes for the maintenance of the red blood cell are already apparent and one of these, the mechanism by which ferrous hemoglobin is kept in a functional condition for oxygen transport will be discussed. However, such important processes as the slow but continuous accumulation of  $K^+$  into the red blood cell against a concentration gradient of  $K^{+110}$  and the preservation of selective permeability of the cell membrane will not be considered here because their link with biochemical events is still not clear.

*Spontaneous Formation of Ferric Hemoglobin (Methemoglobin)* In normal individuals the ferric hemoglobin of the blood may vary from zero concentration up to 0.5 per cent of that of ferrous hemoglobin. As we shall see below, a reducing mechanism is present in the red cells to change the ferric hemoglobin back to the ferrous hemoglobin, that is, back to the functional state for oxygen transport. So the level of ferric hemoglobin in the cells is due to the rate at which ferrous hemoglobin is oxidized and the rate at which it is reduced back again.

Ferric hemoglobin is normally produced at a low, constant rate. For example, hemoglobin of normal human hemolyzed erythrocytes maintained in a saline buffer at pH 7.4 at 37°C, in the presence of 95 per cent air and 5 per cent carbon dioxide, was completely converted to ferric hemoglobin in five days.<sup>111</sup> What is surprising is that this rate is so low. We have considered above, the magnetic data which show that the addition of oxygen to ferrous hemoglobin brings about a profound change in electronic configuration with pairing of all the unpaired electrons, and this pairing has been suggested to be connected with the prevention of oxygen from accepting an electron from the ferrous iron. How the ferric hemoglobin arises is not known.

It might be postulated that, for such a transfer of an electron to occur, all that would be necessary would be a momentary loosening of the linkage between the heme iron and the group on the protein to which it is normally attached. This transfer might occur at the moment when an  $O_2$  molecule was being added to ferrous hemoglobin since it has been shown that the rate of methemoglobin formation is proportional to the amount of ferrous hemoglobin rather than to the amount of oxyhemoglobin. Apparently once the  $O_2$  is attached, the bonding of the iron to the globin in oxyhemoglobin is stabilized.

If agents such as amyl nitrite or propiophenone are added to the blood stream a methemoglobinemia is produced. These agents bring about the oxidation of ferrous to ferric hemoglobin. After a time the ferric hemoglobin is reduced back to ferrous hemoglobin. About 0.5 Gm. of ferric hemoglobin in 100 cc. blood per hour are reduced *in vivo* by the enzymes of the normal red cell according to the estimates of Eder, Finch and McKee.<sup>111</sup>

When this reducing mechanism is improperly functioning, too much ferric hemoglobin may accumulate in the cells and result in primary or congenital methemoglobinemia. Sievers and Ryon<sup>112</sup> have demonstrated that the congenital methemoglobinemia is caused by a slow rate of reduction within the red cell rather than by a process which speeds up the rate of oxidation of the hemoglobin as a result of certain drugs. (In general, drugs which bring about oxidation are those which

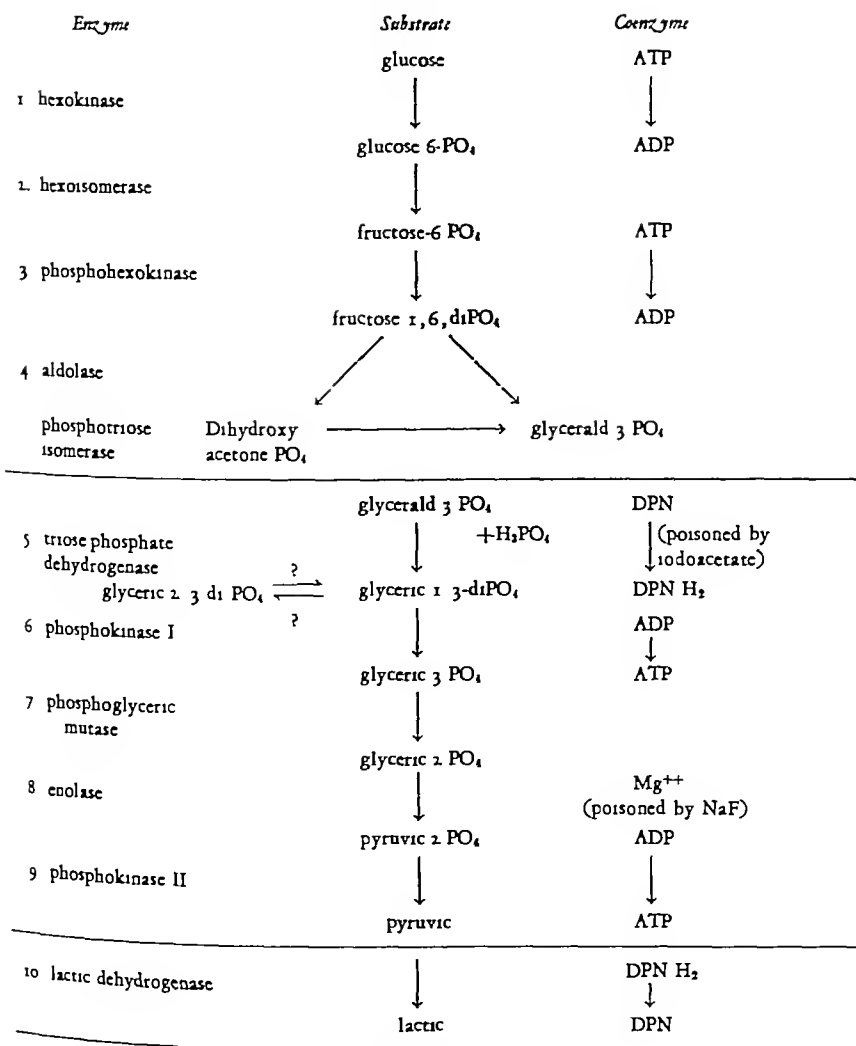

denature the globin, giving rise to hemes which may act as catalysts for oxidation with oxygen <sup>113 114</sup>)

*Glycolytic System of Enzymes and Reduced DPN* In general, the energy released in a mature red cell appears to be derived primarily from the conversion of glucose to lactic acid (fig 5) When glucose is added to red cells lactic acid can be isolated in amounts equivalent to 60-90 per cent of the glucose which has disappeared <sup>11</sup> The glycolysis  $Q_{O_2}^{N_2}$  is + 0.25 and its rate is the same in  $O_2$  as in  $N_2$  The  $O_2$  consumption of the red cells is normally minute, the  $Q_{O_2}$  being -0.05 (i.e., the cu mm  $O_2$  taken up per mg dry wt of red cells per hour) It is not known what material is being oxidized at this slow rate Another enzyme system which has been studied by Dickens (fig 6) appears to oxidize glucose 6-phosphate in a series of oxidative decarboxylations for which the coenzyme required is triphosphopyridine nucleotide (TPN) Parts of this enzyme system have been demonstrated in the red cell This system appears to be of minor importance normally, although in the presence of methylene blue Gibson believes it may play a prominent role in methemoglobin reduction

Two high energy compounds, namely, ATP (adenosine triphosphate) and DPN- $H_2$  (reduced coenzyme) are produced during glycolysis Equation 11 (fig 5) summarizes the process of glycolysis through pyruvate Let us first consider the ATP It is seen from this equation that to bring about the conversion of one glucose molecule to two molecules of pyruvic acid, one must prime the reaction with two high-energy phosphate molecules in the form of ATP The ATP molecules are required for the phosphorylation of steps 1 and 3 (fig 5) However at steps 6 and 9 a total of four high-energy ATP molecules is generated, per glucose molecule broken down by glycolysis The overall gain of high energy phosphate per glucose molecule is thus the conversion of 2 ADP to 2 ATP molecules These high-energy phosphate molecules are in part required for the phosphorylation resynthesis of the pyridine, adenine and riboflavin nucleotides to compensate for the slow hydrolytic breakdown *in vivo* of the coenzymes containing them

The other high-energy compound produced in glycolysis is DPN  $H_2$ , formed by the reduction of DPN at the triose phosphate dehydrogenase stage (step 5) For every glucose molecule glycolyzed through this stage, two molecules of DPN  $H_2$  are formed Since one molecule of DPN- $H_2$  can reduce two hemes of ferric hemoglobin to the functional ferrous hemoglobin, this means that a molecule of glucose according to this scheme would be capable of bring about the reduction of four hemes of ferric hemoglobin It can be calculated that reduction of ferric hemoglobin at the maximum rate of the red cells (0.5 g per 100 cc. blood per hour) would require only about one-tenth the glucose that actually is used up by the red cell If DPN- $H_2$  does not reduce ferric hemoglobin, then at step 10 it will tend to reduce pyruvic to lactic acid However, the reverse reaction of lactic to pyruvic may occur at a reasonable rate only if a relatively high concentration of lactate is present or if a very low concentration of DPN- $H_2$  is present From the redox levels ( $E'_0$  for lactate-pyruvate = -0.180 V,  $E'_0$  for DPN - DPN  $H_2$  = -0.29 V) one may calculate that for a system at equilibrium containing equal concentrations of lactate and pyruvate, the DPN- $H_2$  concentration would only be  $10^{-3}$  that of the

Abbreviations ATP = adenosine triphosphate ADP = adenosine diphosphate DPN = coenzyme I or diphosphopyridine nucleotide or adenine nicotinamide dinucleotide DPN-H<sub>2</sub> = reduced DPN

FIG. 5—STEPS IN THE EMBDEN MEYERHOF GLYCOLYTIC SCHEME (all steps are reversible)

lactate concentration. In other words, if lactate were to be the energy source for the reduction of DPN, the DPN-H<sub>2</sub> would continue to be formed only if it were

rapidly removed from the neighborhood of the enzyme, or if the DPN-H<sub>2</sub> were rapidly oxidized

From these considerations it follows that for the reduction of ferric hemoglobin the production of the reduced coenzyme (DPN-H<sub>2</sub>) from DPN at either the triose phosphate dehydrogenase step or at the lactic dehydrogenase step is essential in the red cell. This has been demonstrated indirectly by Dische,<sup>115</sup> and more directly by Gibson.<sup>116</sup> For example, iodoacetate (0.002 M) is known to poison triose phosphate dehydrogenase and not lactic dehydrogenase. If glucose is used as substrate then in the presence of iodoacetate no reduction of ferric hemoglobin can be found, but addition of lactate can still bring about ferric hemoglobin reduction in the expected ratio of 1 lactate oxidized to 2 ferric hemoglobin reduced. On the other hand, if 0.01 M NaF (which poisons the enolase step by removing Mg<sup>++</sup>, forming the complex MgFPO<sub>4</sub>) is added to the red cells, together with glucose, then reduction can still go on because the triose phosphate dehydrogenase is still active, in this experiment glycemic acid phosphate is found to arise as expected (equation 12, fig. 5). Under normal conditions in the red cell it would appear that reduction of DPN is brought about primarily by the triose phosphate dehydrogenase enzyme.

*Flavine Activity in Methemoglobinemia* In order to reduce ferric hemoglobin to the ferrous state, electrons must pass from DPN-H<sub>2</sub>, the reduced coenzyme, to ferric hemoglobin. This electron transfer does not occur directly to any appreciable extent, and electron mediators appear to be necessary. One important mediator, from analogy with other tissues, is probably a diaphorase enzyme which has flavine adenine dinucleotide as its prosthetic group. It is difficult, however, to conceive that the rate of diffusion of a protein enzyme would be sufficiently rapid to bring about reduction of ferric hemoglobin. Rather does it seem reasonable to postulate that flavine mono- or dinucleotide molecules are present in solution, or that the flavine prosthetic groups are only loosely attached to the protein, i.e., the flavine enzyme is readily dissociated. Thus one may picture the electron as passing from DPN-H<sub>2</sub> → flavine enzyme → flavine nucleotide → ferric hemoglobin.

Determinations of the flavine adenine dinucleotide in normal red cells show it to be in a concentration one-hundredth that of the nicotinamide coenzymes. One suggestion to explain this low content of flavine in normal red cells is that reduced flavine, especially that not attached to proteins, is autooxidizable and can form H<sub>2</sub>O. If much flavine were present, the H<sub>2</sub>O<sub>2</sub> produced might bring about the formation of ferric hemoglobin and the H<sub>2</sub>O<sub>2</sub> would also tend to oxidize the porphyrin ring. It is interesting to note in this connection that in the methemoglobinemias examined by Gibson<sup>116</sup> the metabolic lesion appeared to be caused by a lack of a diaphorase flavine enzyme, rather than by a lack of flavine dinucleotide. This fits in with the findings of Eder et al.<sup>111</sup> who observed no decrease in flavine dinucleotide concentration (as measured by the d-amino oxidase activity) in their methemoglobinemia patients.

*Catalysis of Reduction of Ferric Hemoglobin by Methylene Blue* When as little as  $5 \times 10^{-6}$  M methylene blue is added to red cells in the presence of glucose, the uptake of O<sub>2</sub> is accelerated more than ten fold.<sup>116</sup> Under these conditions, Gibson<sup>116</sup>

found that ferric hemoglobin was reduced at a rate ten times the normal, and with lactate the reduction rate was twice the normal. Glucose brought about the reduction of over 6 moles of ferric heme in the presence of 0.02 M NaF, although the theoretical maximum possible in the glycolytic scheme would be only 4 moles. This suggests that methylene blue is acting as a catalyst for glucose oxidation, which is coupled with reduction of ferric hemoglobin. Gibson postulates that such an oxidation might well take place through the Dickens scheme (fig. 6), where TPN-H<sub>2</sub> could be produced and serve as electron donor.

In general, the action of methylene blue might be explained by its catalyzing the transfer of electrons from reduced coenzymes to ferric hemoglobin. In the glycolytic scheme DPN-H<sub>2</sub> would be involved, and in the Dickens scheme of hexosephosphate oxidation TPN-H<sub>2</sub> would be involved.

FIG. 6—DICKENS SCHEME<sup>117</sup> FOR THE STEPWISE OXIDATION OF GLUCOSE PHOSPHATE

The enhancement of the reducing ability of normal red cells and also of abnormal red cells of methemoglobinemia cases, when methylene blue was added has led to its use in treatment. Finch<sup>118</sup> has recommended oral administration of 200–300 mg of methylene blue per day to adults with congenital methemoglobinemia, this dose being sufficient to decrease the methemoglobin of the red cells to 1 per cent or less of the total hemoglobin. In this connection it would be interesting to study the effect of feeding riboflavin itself to such patients.

To what extent the tricarboxylic acid cycle is present in the mature erythrocyte cannot as yet be answered. Studies on intact dog red cells by Spicer et al.<sup>128</sup> indicate that citric and succinic acids are ineffective in bringing about reduction of ferric hemoglobin. Whether these substances cannot penetrate the red cell or cannot be metabolized is not known. However, fumaric and malic acids were found to be effective in the reduction of ferric hemoglobin. These results suggest that in the

is present a fumarate hydrating enzyme which converts fumarate to malate and that there is also present a malic dehydrogenase enzyme which oxidizes malate to oxalacetate. This oxidation to oxalacetate is coupled with the reduction of DPN to DPN-H<sub>2</sub>. Nossal<sup>119</sup> has shown that fumarate increases the O<sub>2</sub> uptake of the red cells slightly but more so in the presence of methylene blue. The O<sub>2</sub> uptake in the presence of methylene blue was greater with fructose than with glucose, less with mannose and still less with galactose, ribose and arabinose.

*Reduction of Ferric Hemoglobin by Ascorbic Acid* It has been found in congenital methemoglobinemias that the ascorbic acid of the blood is decreased from a normal value of about 1.5-2.0 mg per 100 cc down to about 0.25 mg/100 cc. The glutathione of the red cells is also found to be decreased from about 40 mg/100 cc blood to 20 mg. Despite adequate diets the ascorbic acid remains low in these cases, suggesting that it might be utilized to some extent in the reduction of ferric hemoglobin.<sup>112</sup>

It has been noted that the maximum ferric hemoglobin arising in congenital methemoglobinemia is between 30-40 per cent of the total hemoglobin. When ferrous hemoglobin solutions are injected intravenously, ferric hemoglobin is formed, likewise if ferric hemoglobin solutions are injected intravenously an equilibrium is established at about 40 per cent ferric hemoglobin. A reducing mechanism must be present which prevents ferric hemoglobin from increasing above this value. It has been suggested that ascorbic acid is the functional reducing agent. Because of the relatively poor reducing ability of ascorbic acid, its functioning becomes appreciable only when a relatively high ferric hemoglobin concentration has developed. Calculations of Sievers and Ryon<sup>112</sup> indicate that the reducing ability of ascorbic acid is far greater than can be accounted for by even stoichiometric reaction. It is possible to explain this action by assuming that ferric hemoglobin in the red cell reacts directly with ascorbic acid and that the dehydroascorbic acid thus formed diffuses back into the blood stream and is reduced to ascorbic acid by other body cells. Satisfactory results in decreasing the methemoglobinemia down to 8-10 per cent methemoglobin have been reported when large doses of ascorbic acid (100-500 mg daily) were fed.

*Glycolysis in Hemolysates* It was observed by Warburg and Christian<sup>120</sup> that after hemolysis of the red cell glucose was no longer utilized and endogenous respiration soon ceased. No reduction of ferric hemoglobin occurred in hemolysates even in the presence of methylene blue. However, if glucose-6-PO<sub>4</sub> were used as substrate then glycolysis could proceed slowly. Evidently some enzyme or coenzyme which was required for the phosphorylation of glucose was destroyed in the hemolysate. Gutman, Jandorf and Bodansky<sup>95</sup> confirmed this work. In addition they found that DPN tended to be hydrolyzed in the hemolysate and that this hydrolysis was diminished by the addition of nicotinamide. They observed considerable reduction of ferric hemoglobin when hexose diphosphate or lactate was used as substrate in the presence of nicotinamide and methylene blue.

The reason for the nonphosphorylation of glucose in hemolysates is suggested by Dische to be due to the absence of ATP.<sup>121</sup> Dische could show that in the presence of 0.02 M NaF or 0.01 M bromoacetate, ATP transphosphorylated with

glucose to form hexosephosphate and triosephosphates so the biochemical lesion in the hemolysate did not lie in the steps above the triosephosphate stage (fig. 5). In a study of the glycolytic enzymes of brain hemogenate, Racker and Krimsky<sup>12</sup> found that triosephosphate dehydrogenase at step 5 (fig. 5) appeared to be the most readily damaged of these enzymes, even being inactivated by traces of iron salts. If the triosephosphate dehydrogenase enzyme were inactivated by hemolysis, it would offer a satisfactory explanation for the nonutilization of glucose since no ATP could then be formed and glucose could not be phosphorylated.

It may be noted in conclusion to this chapter that the metabolic problems of the red cell are not merely of theoretic interest. One of the major practical considerations of wartime research was the development of conditions for the maintenance of the erythrocyte *in vitro* so that whole blood might be shipped to the fighting fronts.<sup>108-123</sup> Under the best conditions, satisfactory preservation of the blood for twenty-one to thirty days was obtained by using an acid-citrate-dextrose\* solution as developed by Loutit & Mollison. The temperature for preservation was 4-10°C. Citrate was used as anticoagulant, glucose was added to maintain glycolysis, and the final acidity of the blood at pH 7.0 seemed to stabilize the enzymes and minimize the ATP changes.

Another practical problem of greater complexity is the maintenance of erythrocytes at 37°C. in the study of malarial infections with the hope that a knowledge of the nutritional requirements of these organisms might lead to a rational chemotherapy.<sup>124-125</sup>

#### SUMMARY

The erythrocyte is a unit of protoplasm highly specialized for the functions of  $O_2$  and  $CO_2$  transport but still containing sufficient repair systems for maintaining itself for about 120 days.

The erythrocyte develops through a complex series of changes, arising from a reticular cell of the bone marrow and differentiating into an actively synthesizing and dividing nucleated cell. After a time the cell stops dividing, the nucleus begins to degenerate and a differentiation takes place in the cytoplasm, the complex mixture of cytoplasmic proteins including mitochondria being replaced almost but not completely by a single kind of protein, namely, hemoglobin.

The functions of several of the anatomic features of the hemoglobin molecule are considered. The hemoglobin molecule has a molecular weight of 68,000 with 4 planar heme units which lie parallel to each other, two being on the proximal and two on the distal surface of the globin. The globin appears to be made up of 4 polypeptide layers with the planar heme units lying perpendicular to the polypeptide layers.

\* Trisodium citrate 2  $H_2O$  = 2.20 g

Citric acid U.S.P. = 0.80 g

Dextrose U.S.P. = 2.45 g

Dilute to 100 cc. with  $H_2O$ . The pH of this solution is about 5.0. Because of its acidity it can be autoclaved without caramelizing the dextrose. This solution is used in the proportion of 15 cc. per 100 cc. blood (generally 75 cc. of fluid per 500 cc. of blood).

The heme units possess a resonating ring structure which stabilizes the unit. The two vinyl groups on the periphery of the heme appear to be necessary if an iron atom is to be inserted into the newly formed protoporphyrin ring. The two ionized propionic acid groups also at the periphery of the heme, appear to be required for orienting and attaching the heme unit to two strongly basic groups of the globin, possibly guanidine groups of arginine. The attachment of the iron of heme is postulated to be to an imidazole nitrogen of a histidine residue of the globin. This latter attachment is by itself a weak bonding but is stabilized not only by the coulombic attraction of the ionized propionic acid groups but also by the Van der Waals forces between the globin and the planar resonating porphyrin.

The attachment of the iron to the imidazole group endows the iron of the heme with the property of combining with  $O_2$  reversibly, the addition of  $O_2$  being connected with a pairing of all the unpaired electrons in the complex. Probably, as a consequence of this pairing of electrons, the  $O_2$  does not act as an oxidant as it would if the special iron link to globin were destroyed. The iron of the heme is bound to 6 atoms or atom groups. It binds 4 nitrogens of the protoporphyrin in the plane of the ring. Below the plane of the ring it binds one nitrogen of the imidazole group, and above the plane of the ring it may then bind  $O$  reversibly. The second nitrogen of the imidazole group is postulated to change its ionization with a change of oxygenation of the hemoglobin, this change in ionization makes possible the conversion of some 50 per cent of the  $CO_2$  transported in the blood to bicarbonate ion, without appreciably changing the pH of the blood. A zinc protein, carbonic anhydrase, is present in the erythrocytes to catalyze the normally slow hydration-dehydration of the  $CO_2-H_2CO_3$  system.

How this non-nucleated erythrocyte is maintained in a functional state for a life span of 120 days is poorly understood. The erythrocyte has a very low  $O_2$  utilization which is compatible with the fact that the mitochondria, which are believed to be the seat of cytochrome oxidase activity, are absent. However, there is present a rather complete glycolytic system which appears to play a major role in the metabolic life of the mature erythrocyte. Hemoglobin is slowly converted in the intact erythrocyte to ferric hemoglobin, i.e., methemoglobin. The methemoglobin is reduced back to the functional ferrous form by reduced diphosphopyridine nucleotide arising during glycolysis. Riboflavin enzymes appear to act as the intermediators between reduced DPN and methemoglobin. The pyridine and flavine enzymes which are slowly undergoing hydrolysis are regenerated by adenosine triphosphate produced in glycolysis. Catalase is present, probably to protect the heme units of hemoglobin against  $H_2O_2$ , the hemes being especially vulnerable to peroxidative attack at the methene links.

# BLOOD CARBONIC ANHYDRASE ACTIVITY IN ANEMIA, WITH A NOTE ON POLYCYTHEMIA VERA

By H D LEWIS, M D , AND M D ALTSCHULE, M D

*With the technical assistance of M TAYLOR*

THE ERYTHROCYTES of the blood contain a number of respiratory enzymes, one of which, carbonic anhydrase, is important in the transport of carbon dioxide. The conversion of carbon dioxide derived from the tissues to bicarbonate in the blood, and the breakdown of bicarbonate to release carbon dioxide in the lungs could not proceed at a rate compatible with health if it were not for the presence of carbonic anhydrase in the red blood cells. This enzyme, widely distributed in nature, is especially abundant in mammalian erythrocytes. Since the enzyme in the blood is contained wholly within the erythrocytes, it is apparent that the carbonic anhydrase activity of the blood might be abnormal in anemia. Although earlier workers have investigated the blood carbonic anhydrase activity in anemic blood,<sup>1-3</sup> their studies were carried out by means of methods which were not strictly quantitative and which had no significance for respiratory function at body temperature. Accordingly it was considered desirable to study this matter again, using a new method.

## MATERIALS AND METHODS

One hundred and twelve observations were made on 85 patients, the latter for the most part were patients with anemias of various types and degrees. Some patients not anemic, were also included in order to control phenomena associated with anemia such as icterus, bone marrow disease, etc. Five of the patients studied had polycythemia vera. The ages and diagnoses are in the tables. All studies were made on venous blood at 37 C by means of a method described elsewhere.<sup>4</sup> The method is a modification of that of Mitchell et al.<sup>5</sup> in that the Warburg apparatus is used; observations are made at 37 C, and calculations of activity are made by extrapolation to undiluted blood from measurements made on three dilutions. In each instance measurements were made in duplicate using three different dilutions of blood so that six measurements were made on each sample. Erythrocyte counts and measurements of hemoglobin content and hematocrit were made on each sample of venous blood used for the estimation of carbonic anhydrase activity. The findings in normal subjects by means of this method<sup>4</sup> are summarized in table 1.

## OBSERVATIONS

### *Pernicious Anemia*

Of the 10 patients studied, 8 were anemic when first seen, the other 2 having responded completely to treatment given previously. All patients studied while anemic showed levels of carbonic anhydrase which were in the normal absolute range, i e., they lay between 1.1 and 2.4 units per ml. of blood (table 2, fig 1).

From the Medical Service and Medical Research Laboratories, Beth Israel Hospital, and the Department of Medicine, Harvard Medical School.

Done in accordance with a contract between the Office of Naval Research, U S Navy, and Harvard University.

In all of the anemic subjects the carbonic anhydrase activity of the blood was high relative to the hemoglobin concentration and erythrocyte counts, in all but 2 the carbonic anhydrase per unit RBC was also above the upper limit of normal, 1 c, 58, at some time (fig. 2). During the course of treatment, absolute values for blood carbonic anhydrase activity rose, however, since hematocrits, hemoglobin levels and erythrocyte counts increased several times, the ratio between carbonic anhydrase activity and these measurements decreased toward normal (table 2, fig. 2). Normal relationships between enzyme activity and hematologic measurements did not regularly obtain, however, until the latter had returned to or almost to normal (table 2, fig. 2).

### *Blood Loss*

Anemia consequent to hemorrhage from peptic ulcer or from carcinoma of the stomach, colon or bladder was associated with a decrease in blood carbonic an-

TABLE 1—Observations in Forty-two Normal Subjects

	Range	Average
Hematocrit (per cent erythrocytes)	38.0–56.0	45.2
Hemoglobin (grams per ml blood)	0.133–0.199	0.138
Erythrocytes (billions per ml blood)	3.82–5.93	4.87
Carbonic Anhydrase (units per ml blood)	1.2–2.6	1.8
Carbonic Anhydrase (units per ml erythrocytes)	2.6–5.8	4.05
Carbonic Anhydrase (units per gram of hemoglobin)	8–17	13
Carbonic Anhydrase (units per billion erythrocytes)	0.25–0.56	0.37

hydrase activity (table 3, fig. 3). The fall in activity of the enzyme paralleled decreases in hematocrits, hemoglobin levels and erythrocyte counts, so that the ratio of carbonic anhydrase activity to these measurements was in the normal range in every instance (table 3, fig. 4). Neither the cause of the bleeding nor its chronicity influenced the level of activity of the blood carbonic anhydrase, the 3 patients (Cases 15, 18 and 20, table 3) in whom the anemia had been present for months with a resultant decrease in cell size, showed relationships between enzyme activity and the various other measurements made on the blood which were similar to those found in patients with bleeding of recent onset, changes in cell size had no significant effect.

### *Infection*

Slight anemia was encountered in 10 patients in association with chronic febrile diseases, these included rheumatoid arthritis, rheumatic fever, pyelonephritis, pulmonary tuberculosis and ulcerative colitis. The carbonic anhydrase activity was slightly lowered but in every case lay within the range of normal in keeping with the mildness of the anemia (table 3, figs. 4 and 5), the presence of persistent diarrhea (Cases 30 and 31, Table 3) did not influence the findings.

*Uremia*

The anemia of uremia likewise was found to be accompanied by a decrease in blood carbonic anhydrase level, the diminution in activity of the enzyme in the blood paralleled the severity of the anemia so that the ratio between carbonic

FIG 3—ANEMIA OF BLOOD LOSS POLYCYTHEMIA VERA RELATION BETWEEN CARBONIC ANHYDRASE ACTIVITY OF WHOLE BLOOD AND HEMATOCRIT The crellated dots indicate polycythemia vera The parallelogram indicates the normal range the dotted line is drawn from the origin through the average normal value

upper range of normal The presence of icterus caused no deviation from the carbonic anhydrase activity expected on the basis of the hematological findings

#### *Leukemia and Allied Conditions*

Anemia was present in all of the 17 patients studied, with the exception of one, who had acute myelogenous leukemia (table 3, Case 53) When anemia was present,

the blood carbonic anhydrase activity was reduced as a rule to or below the lower range of normal, the ratio between enzyme activity and hematocrits, hemoglobin levels and erythrocyte counts remaining normal (table 3, fig 7) In 4 patients, however, (table 3, Cases 45, 48, 49, 50) who comprised half of the patients with

FIG 4.—ANEMIAS OF BLOOD LOSS, INFECTION AND UREMIA. POLYCYTHEMIA VERA. RELATION BETWEEN CARBONIC ANHYDRASE ACTIVITY OF ERYTHROCYTES AND HEMATOCRIT. The cross-hatched area is the normal range for carbonic anhydrase activity per ml erythrocytes, the heavy line through it is the level of the normal mean value.

FIG 5.—ANEMIAS OF INFECTION AND OF UREMIA. RELATION BETWEEN CARBONIC ANHYDRASE ACTIVITY OF WHOLE BLOOD AND HEMATOCRIT. The circled dots indicate uremia. The parallelogram indicates the normal range, the dotted line is drawn from the origin through the average normal value.

chronic myelogenous leukemia, the blood carbonic anhydrase level was high in the normal range in spite of the presence of anemia, so that the ratio between enzyme activity and hematocrits, hemoglobin levels and erythrocyte counts was abnormally high.

#### *Miscellaneous Anemias*

Studies on instances of various uncommon types of anemia revealed, with a few exceptions, blood carbonic anhydrase levels in or below the lower normal range.

decreases in enzyme activity paralleled the severity of anemia so that the ratio between carbonic anhydrase level and the hematocrits, hemoglobin levels and

FIG 6—HEPATIC DISEASE RELATION BETWEEN CARBONIC ANHYDRASE ACTIVITY OF WHOLE BLOOD AND HEMATOCRIT The crellated dots indicate jaundice, the parallelogram indicates the normal range, the dotted line is drawn from the origin through the average normal value

FIG 7—LEUKEMIA RELATION BETWEEN CARBONIC ANHYDRASE ACTIVITY OF WHOLE BLOOD AND HEMATOCRIT The parallelogram indicates the normal range the dotted line is drawn from the origin through the average normal value

erythrocyte counts were normal. Exceptions to this finding were encountered in 2 patients with dietary malnutrition (table 3, Case 77) and 2 of the 4 instances of

refractory anemia (table 3, Cases 62 and 64), the 2 other cases of refractory anemia (table 3, Cases 63 and 65) revealed ratios in the normal range

### *Polycythemia Vera*

Patients with polycythemia vera showed values for blood carbonic anhydrase activity high in or above the normal range, depending on the severity of the condition (table 3, fig 3) The ratios between enzyme activity and the hematocrits, hemoglobin levels and erythrocyte counts were normal (fig 4)

### DISCUSSION

The present study for the most part is in qualitative agreement with the earlier observations of Lambie<sup>2</sup> on anemia. Different types of anemia vary in regard to the relation between red cell mass and carbonic anhydrase activity of the blood. In the commonly encountered anemias consequent to loss of blood, infection and uremia and probably also in the less common aplastic and hemolytic anemias, a decrease in erythrocytes signifies not only a parallel loss of hemoglobin, but also a corresponding diminution in carbonic anhydrase activity of the blood. The same condition also obtains in most patients with anemia associated with hepatic disease and with leukemia and allied conditions. On the other hand, in patients with pernicious anemia and in some instances of refractory anemia, of hepatic disease and of myelogenous leukemia, the blood carbonic anhydrase activity remains in or only slightly below the normal range in spite of marked decreases in hematocrit, hemoglobin level and erythrocyte count. Patients with pernicious anemia have extremely high blood carbonic anhydrase activity relative to erythrocyte count and exhibit levels of enzyme activity which may be several times as high as that shown by patients with comparable hemoglobin or hematocrit levels associated with anemia of blood loss, infection or uremia. The reason for this difference is not known. In contradistinction to earlier workers<sup>1-3</sup> no evidence was found to support the concept that icterus increases blood carbonic anhydrase activity.

The precise significance of the findings of the present study cannot be stated in the absence of complete information as to the physiological function of the blood carbonic anhydrase. Theoretical considerations indicate that its property of accelerating the reaction  $\text{H}_2\text{O} + \text{CO}_2 \rightleftharpoons \text{HCO}_3^-$  is essential for the prevention of accumulation of carbon dioxide in the body. It appears, therefore, that under the conditions of accelerated blood flow through the tissues and lungs which obtain in anemia,<sup>6</sup> the need for carbonic anhydrase is greater than normal.

There is no experimental evidence available at present which proves that loss of blood carbonic anhydrase activity definitely causes dyspnea. Sulfanilamide inhibits carbonic anhydrase and therefore observations on sulfanilamide intoxication are pertinent to the problem of dyspnea. The clinical observation that the administration of sulfanilamide causes increased respiratory activity,<sup>7-9</sup> and intolerance to exercise<sup>10</sup> and to inhalation of carbon dioxide,<sup>11</sup> is difficult to interpret, in clinical conditions of sulfonamide intoxication not only is the activity of the carbonic anhydrase of the blood depressed, but that of the renal tubular carbonic anhydrase probably is also, with the consequent development of acidosis.

due to loss of base. Changes in blood and urinary chemistry over a period of time after administration of sulfanilamide are so complicated as to suggest the effects of the action of several factors.<sup>7-9</sup> The work of Wood and Favour<sup>9</sup> showed, however, that the injection of sulfanilamide intravenously rapidly causes inhibition of the enzyme in the blood and that immediately thereafter lowering of the arterial blood carbon dioxide content occurs. This observation suggests that decreased carbonic anhydrase activity in the blood may cause or contribute to dyspnea through impaired removal of carbon dioxide from the tissues, accumulation of carbon dioxide in the brain causes stimulation of respiration with consequent hyperventilation and immediate lowering of arterial blood carbon dioxide tension. Apparently accumulation of carbon dioxide in the blood through retardation of its excretion in the lungs is not a factor. The fall in arterial blood carbon dioxide level which occurs as a consequence of inhibition of carbonic anhydrase activity by administration of sulfanilamide resembles the decrease in blood carbon dioxide usually found in patients with anemia<sup>6</sup>, however, in these patients additional factors, such as anoxia and also impaired heat dispersal consequent to cutaneous vasoconstriction, also cause hyperventilation. Data now available do not permit distinction between hyperventilation possibly due to lack of carbonic anhydrase and that consequent to other factors in patients with anemia.

The numerous and complex cardiovascular and respiratory compensations in anemia have been discussed elsewhere.<sup>6</sup> The importance of erythrocytes in carbon dioxide transport is established. Although the red blood cells hold less carbon dioxide than plasma, they take up approximately 40 per cent of the carbon dioxide added to the blood as it circulates through the tissues. The mechanisms whereby erythrocytes are able to hold so much carbon dioxide at a pH of 7.1 in competition with plasma whose pH is 7.4 have not been delineated completely. Several factors have been studied. Hemoglobin is a buffer, change in its acidity when it is reduced accounts for an important part of the carbon dioxide carrying power of erythrocytes, carbonic anhydrase is important in this phenomenon, for without the enzyme bicarbonate cannot enter the red cells in a normal fashion.<sup>12-13</sup> Similarly the chloride shift cannot occur at a normal speed in the absence of adequate amounts of active carbonic anhydrase in erythrocytes.<sup>13-15</sup> Another possible factor, not completely studied, is the transport of carbon dioxide in the form of carbamates in combination with hemoglobin and possibly other substances, it is probable that still other factors also operate. Whether deficiency of blood carbonic anhydrase interferes with carbon dioxide transport solely through impairment of mechanisms involving hemoglobin or whether other factors also play a part is not known, the lack of complete knowledge as to the precise function of carbonic anhydrase in blood gas transport makes it impossible at the present time to examine critically the role of the enzyme in the production or prevention of symptoms.

Although hemoglobin is essential for oxygen transport and very important in carbon dioxide transport, the fact remains that patients with pernicious anemia have long been known to tolerate exertion without the development of severe dyspnea even when the blood hemoglobin level is as low as that which is associated with dyspnea in patients with some other chronic anemias, such as those consequent to slow loss of blood. This fact indicates the importance of factors

other than hemoglobin level in the genesis of the dyspnea of anemia and suggests that the observed differences in blood carbonic anhydrase activity might be significant in this regard

In polycythemia vera, the increases in blood carbonic anhydrase activity which parallel increases in hematocrit apparently have no vital importance in the altered cardiorespiratory function which occurs in this disease

### SUMMARY AND CONCLUSIONS

Measurements of blood carbonic anhydrase activity were made in patients with a variety of blood dyscrasias, using a new method. In patients with anemia due to loss of blood, infection and uremia, and in most of those with anemia associated with liver disease and leukemia, a constant relation was found between blood carbonic anhydrase activity and the hematocrit, the same holds in polycythemia vera. In patients with pernicious anemia, and in some with refractory anemia, and anemias associated with hepatic disease and with myelogenous leukemia, blood carbonic anhydrase activity was in or near the normal range in spite of lowered hematocrit values. The possible relation between these differences among anemias and the tolerance of patients with various anemias to exercise is discussed.

# THE ZINC CONTENT OF WHOLE BLOOD, PLASMA, LEUKOCYTES AND ERYTHROCYTES IN THE ANEMIAS

By BERT L. VALLEE, M.D., AND JOHN G. GIBSON, II, M.D.

WE HAVE previously described our findings of the zinc content of normal whole blood, plasma, leukocytes and erythrocytes.<sup>1</sup> The following zinc concentrations in micrograms (gammas) were found to represent the normal pattern

	<i>Amis</i> in $\mu\text{g}$	<i>S.D.</i>	<i>Unit</i>
Whole Blood	88	$\pm 2.0$	1 cc.
Plasma	30	$\pm 1.6$	1 cc.
Leukocytes	$3.2 \times 10^{-2}$	$\pm 1.3 \times 10^{-2}$	1 million cells
Erythrocytes	$1.34 \times 10^{-2}$	$\pm 0.2 \times 10^{-2}$	1 million cells
Erythrocytes	144	$\pm 2.7$	1 cc.*

Sutton and Nelson,<sup>2,3</sup> and Smith and Larson<sup>4</sup> fed zinc to rats and observed the effect on erythropoiesis and leukopoiesis as reflected in the cytology of the peripheral blood. No measurements of the zinc content of red and white cells were carried out, however. No quantitative measurements of the zinc concentrations of the blood components in patients with anemia are on record. The study herewith reported was conducted on patients afflicted with various types of anemia, in an attempt to elucidate the role of zinc in erythrocytes.

## METHOD

The hematologic techniques and method of measuring blood zinc content have been described previously.<sup>1,5,6</sup> The small number of patients which was studied in each category precluded internal statistical analysis. The mean of the normal series was taken as a point of reference in the evaluation of individual values. Zinc concentrations lying outside of two standard deviations were considered abnormal. For two standard deviations one would expect 1 out of 20 observations on normals to fall outside of these limits.

## MATERIAL STUDIED

Nine patients with pernicious anemia were studied. Samples were obtained prior to or within a few days following institution of liver therapy. Five of these patients were followed over a prolonged period of time while under maintenance therapy with liver extract. A total of 34 blood samples was analyzed.

A second group of patients with various types of anemia was investigated. Five patients were found to have so-called refractory anemia. Three of these patients had white blood cell counts below 2000/mm.<sup>3</sup> Four patients were anemic secondary to hemorrhage: 2 had an anemia of infection, 2 had a sickle cell anemia. 1 patient each had nutritional anemia, iron deficiency anemia, splenic anemia, infectious mononucleosis, and Cooley's anemia. There was a total of 23 blood samples.

## RESULTS

Table 1 summarizes the zinc concentrations found in whole blood, plasma, leukocytes and erythrocytes in patients with anemias other than pernicious anemia.

From the Department of Medicine, Harvard Medical School and the Medical Clinic of the Peter Bent Brigham Hospital, Boston, and the Department of Physics, Massachusetts Institute of Technology, Cambridge, Mass.

This study was supported by a grant in aid from the National Institute of Health.  
\* 1 cc. of erythrocytes packed by centrifuging at 3000 r.p.m. for 30 minutes.

mia Table 2 presents similar data obtained from patients with pernicious anemia. The values for the zinc concentrations contained in 1 ml of whole blood due to plasma, leukocytes and erythrocytes are shown in tables 3 and 4. These values were calculated as previously described.<sup>1</sup>

The abnormal red blood cell findings are essentially limited to patients with pernicious anemia and possibly sickle cell anemia. In pernicious anemia, in contrast to other forms of anemia, in which zinc concentrations were found to be in the

normal range, the unit red blood cell zinc concentration prior to therapy is significantly increased, but returns to within normal limits with successful therapy.

#### DISCUSSION

The over-all limitations of the technique employed (chemical analysis and hematology) have been found to be defined by an error of about  $\pm 15$  per cent.<sup>1</sup>

The direct measurements for whole blood, plasma, red cells and white cells, in

the group of secondary anemias, given in table 1, are graphically depicted in figure 1

† With reference to institution of therapy

Seventeen of the 23 whole blood zinc measurements (fig 1A) are shown to fall within  $\pm 2$  standard deviations of the mean of our normal series. Case 49 had a

high whole blood zinc due to an increased plasma zinc, while the red blood cell zinc was normal. Case 14 was refractory to all therapy. The whole blood zinc was just above the range of the normal series though within the possible technical limit of error. In Case 17, three consecutive samples were consistently below the lower limit of normal. While under observation, no diagnosis was established, and

4. Sum of Columns 1, 2, and 3

we are, therefore, because of the singularity of the observation, unable to draw conclusions from these data.

Figure 1B shows the plasma zinc concentrations, all of which are within the limits of normality except Case 49, previously referred to, and Case 106, for no apparent cause.

Figure 1C is a plot of leukocyte zinc content in terms of  $1 \times 10^{-6}$  gamma per million leukocytes. It is apparent that Cases 17, 18 and 62 have a leukocyte zinc

concentration elevated from three to ten times above normal. These patients were considered refractory to all therapy. They all had leukocyte counts below

† With reference to institution of therapy

Explanation of columns the same as in table 3

2000/mm<sup>3</sup>. This was in contrast to Case 95, which was also found refractory to therapy but had a normal zinc concentration of leukocytes which numbered 12,750/mm<sup>3</sup>. We are not at present prepared to interpret the significance and

physiologic implications of these findings which, however, appear striking in contrast to our findings in leukemic cells. In myelogenous and lymphatic leukemia, the zinc concentration of the circulating leukocytes was found to be about 10 per

FIG 1—Distribution of zinc in whole blood, plasma, leukocytes and erythrocytes in patients with anemia other than pernicious anemia. The mean and 2 standard deviations of the comparable normal values are indicated.

cent of normal. Under effective therapy with x ray and urethane the zinc concentration returned to normal levels. No other significant abnormalities in the leukocyte picture are apparent.

Figure 1D depicts the red blood cell pattern in these cases of anemia in relation to our normal series. Cases 95 (refractory anemia) and 98 (sickle cell anemia) show significant elevations above the normal. Cases 106, 133, 66 and 107 have zinc concentrations just above the upper limit of the normal distribution curve. It would require a larger number of observations to determine whether or not this is significant or due to chance scattering. With the exception of these cases, there were no abnormalities in the red cell series of this group.

The changes in zinc concentration observed in pernicious anemia patients (table 2) are apparently due to a marked increase in unit zinc content of erythrocytes which are reflected in the whole blood zinc. Neither plasma zinc nor white blood cell zinc presents any significant deviation from the normal distribution picture. The zinc of leukocytes in samples 21-1 and 57-2 was elevated, due to known technical error. Other leukocyte zinc values were within normal limits (fig. 2A, B, C).

The unit red cell zinc concentrations (calculated per million cells (fig. 2D) and per cc. of packed cells) of untreated patients are elevated significantly above the normal range. Following institution of therapy and after an initial rise, the unit zinc content falls successively over a prolonged period. In Cases 57 and 128, samples were obtained at close intervals. On the 55th and 66th days of sampling, respectively, following institution of therapy, the erythrocyte zinc concentration returned to normal levels, and remained normal thereafter under maintenance therapy. In Case 132, normal levels were obtained within 69 days following institution of therapy. In Case 19, no samples were obtainable between the 40th and 366th days of therapy. Similarly, no samples could be obtained between the 30th and 369th days post-therapy in Case 21. While the earlier samples still showed a definitely increased zinc concentration, samples taken 366 and 369 days after treatment was begun were normal in unit erythrocyte zinc content.

Figures 3, 4 and 5 show the erythrocyte zinc concentration per million cells, the red blood cell count, the per cent reticulocytes and absolute number of reticulocytes, in one ml. of blood as a function of time. Doses of liver therapy, given while under hospital care, are indicated by arrows at the top of each graph.

Case 19 in figure 3 shows a prompt reticulocytosis in response to a test dose of liver. The reticulocyte response which is also shown in terms of the absolute reticulocyte count was accompanied by a prompt rise in red blood cell count which continued when the reticulocyte response subsided. During this period there was a progressive fall in the zinc concentration of red blood cells which eventually reached normal levels. Maintenance therapy had no visible effect on the zinc concentration.

The features of Case 57 (fig. 4) were essentially similar to those just described for figure 3. Therapy was spaced very nearly identically. There was a slight rise in zinc concentration at the height of reticulocytosis. However, this rise is entirely within the limits of technical error. The unit zinc concentration fell to normal levels within 55 days following institution of liver therapy.

Case 127 (fig. 5) differs materially in both character and degree of response from these two instances. Coincidental with therapy, observations on this patient to evaluate the potency of the liver extract used were made. The patient received 1 ml. on 1/14/48, with a subsequent submaximal reticulocyte response. The first

zinc sample was obtained near the height of this reaction. Thereafter, intensive daily therapy with the extract was instituted. This resulted in a good reticulocyte response which became maximal on the 20th day following the first liver injection.

FIG. 2.—Distribution of zinc in whole blood, plasma, leukocytes and erythrocytes in patients with pernicious anemia. The mean and 2 standard deviations of the comparable normal values are indicated.

A prompt rise in total red blood cell count accompanied this phenomenon. The zinc concentration per million cells during this period rose progressively and reached a peak at the height of reticulocytosis and fell concomitantly with it. Thereafter, the zinc concentrations fell to normal levels in a fashion similar to the

FIG 6—Zinc, in gamma  $\times 10^{-3}$  per million red cells, in relation to the red cell count, showing a fall in 4 patients with pernicious anemia under therapy

ones shown in Cases 19 and 57. The normal level was attained within 66 days. In Case 131, where only three samples were obtained, a normal value was found on the 69th day post-therapy.

Whether or not this response of the zinc concentration was related to the particular liver extract used, the dosage given, or whether it is a property of young cells released from the bone marrow in pernicious anemia under the stimulus of liver therapy, we are unable to conclude on the basis of our present observations.

In the 3 cases we were able to follow, the erythrocyte zinc concentration returned to normal levels within 55, 66 and 69 days respectively. This time closely approximates the mean life span of erythrocytes in pernicious anemia as determined with  $N^{15}$  labelled glycine by London, Shemin and Rittenberg.<sup>8</sup> We believe that the change in zinc concentration is probably a function of the replacement of pernicious anemia cells by cells formed under the influence of liver extract, and in effect is an expression of the death rate of the pernicious anemia cell.

Figure 6 shows the unit zinc concentration in red blood cells in micrograms per million cells, in relation to the red blood cell count. The unit zinc concentration reaches the normal level at the time when the red blood cell count has returned to normal, coinciding with a return of the M C V toward normal size. In the secondary anemias, the zinc concentration per unit cells remains normal in spite of low red blood counts.

Red blood cell zinc was also calculated per cc of packed cells. Thereby the increased size of the individual cell was eliminated as a factor which could contribute to the increased zinc concentration of red cells per million cells. A definite increase over the normal zinc concentration is nevertheless noticed. The phenomenon is therefore not simply one of increased cellular mass.

In anemias other than pernicious anemia, zinc and carbonic anhydrase decrease on a slope parallel to that of the drop in hemoglobin. In contrast, in pernicious anemia, the increase of zinc and carbonic anhydrase are inversely proportional to the fall in hemoglobin indicating that the hemoglobin and carbonic anhydrase systems are structurally discrete though functionally related.

In sickle cell anemia, the zinc concentration of erythrocytes was markedly elevated in one out of three samples on 2 patients. The other two samples were above two standard deviations from the normal mean but so close that they could not be thought to be statistically significant. More observations in this condition are required before a definitive statement about zinc distribution can be made.

Zinc is known to be an integral component of the enzyme carbonic anhydrase.<sup>9, 10</sup> The functional significance of this enzyme in the anemias has recently been scrutinized,<sup>11</sup> and the quantitative relationship of zinc and enzyme activity has been determined independently on samples of venous blood, and is being reported in two other communications.<sup>12, 13</sup>

#### CONCLUSIONS

1. The zinc content of whole blood, plasma, leukocytes and erythrocytes was determined in 20 patients with miscellaneous anemias and in 9 patients with pernicious anemia.

2 Unit values for erythrocytes (zinc in gamma per million cells or per cc of packed cells) were within the limits of normality in the anemias, other than pernicious anemia

3 In pernicious anemia, unit values for erythrocytes were significantly elevated above normal. Under successful liver therapy there was a progressive fall in unit value which reached normal when the red blood cell count had risen to normal

4 The rate of decrease in unit zinc value of the circulating red cells in pernicious anemia is comparable to the probable death rate of cells in circulation prior to the institution of therapy

# THE RELATIONSHIP BETWEEN CARBONIC ANHYDRASE ACTIVITY AND ZINC CONTENT OF ERYTHROCYTES IN NORMAL, IN ANEMIC AND OTHER PATHOLOGIC CONDITIONS

By BERT L. VALLEE, M D , HERBERT D. LEWIS, M D , MARK D. ALTSCHULE, M D ,  
AND JOHN G. GIBSON, II, M D

IT HAS been shown that zinc is a component of the carbonic anhydrase molecule.<sup>1, 2</sup> This enzyme has been demonstrated to catalyze the reaction  $\text{H}_2\text{O} + \text{CO}_2 \rightleftharpoons \text{H}_2\text{CO}_3$  in vitro, its molecular weight is approximately half that of hemoglobin,<sup>3</sup> and some of its other physico chemical properties are established.<sup>3, 4</sup> Carbonic anhydrase obtained from ox and sheep blood has been found to contain 31-34 per cent of zinc per unit of dry, active protein, these values having been obtained by means of a diphenylthiocarbazonate method.<sup>1, 2</sup> This method, when applied to human carbonic anhydrase, indicated the presence of 0.164 per cent of zinc, according to Keilin and Mann.<sup>1</sup> Other investigators, using an older and less sensitive technique,<sup>5</sup> reported ox carbonic anhydrase to contain 0.20 to 0.23 per cent of zinc,<sup>6</sup> and later confirmed these results by polarography.<sup>7</sup>

The nature of the bond between the metal and protein, and the chemistry of the enzyme are not understood at present. The enzyme may be inactivated by various substances. Acids separate zinc from its proteinous prosthetic group, this process is irreversible, a finding which led Keilin and Mann<sup>1</sup> to consider the metal to be the active part of the enzyme molecule. When the enzyme is inactivated by long standing, or by manipulation, zinc remains bound to the protein and cannot be removed by dialysis. While the separation of zinc from enzyme protein irreversibly destroys its activity, the inactivation of the enzyme does not necessarily liberate the metal.<sup>1</sup> Under some circumstances, the presence of an excess of zinc may be due, therefore, to the presence of inactivated enzyme retaining its full complement of zinc.

Zinc is found in human plasma, erythrocytes and leukocytes,<sup>8, 14</sup> but carbonic anhydrase activity can be detected in the blood only in erythrocytes.<sup>15</sup> The carbonic anhydrase activity and zinc concentration, determined separately in normal and pathologic human erythrocytes, have been found to vary within relatively narrow limits.<sup>11, 14, 16</sup> The present study was made to investigate the possible correlation of these two erythrocyte parameters in normal and abnormal states of health.

## METHOD

Venous blood samples were obtained as previously described.<sup>17</sup> Aliquots of each sample were studied for their carbonic anhydrase activity and zinc concentration. The enzyme measurement was performed on

From the Medical Clinic Peter Bent Brigham Hospital the Medical Service and Medical Research Laboratories Beth Israel Hospital and the Department of Medicine Harvard Medical School Boston Mass

Part of this work was aided by a grant from the National Institute of Health the remainder was performed in accordance with a contract between Harvard University and the Office of Naval Research U S Navy

whole blood according to the method described by Altschule and Lewis<sup>16</sup>, a large number of control measurements showed no activity in either plasma or leukocytes.<sup>16</sup> The activities found were, therefore equivalent to the carbonic anhydrase content of the red cell mass contained in 1 cc. of whole blood. An attempt was made to keep the interval between venipuncture and analysis at a minimum to avoid inactivation of the enzyme by excessive manipulation or changes in temperature. Measurements of zinc and blood counts were made according to the routine previously employed.<sup>17</sup>

For statistical purposes the normal series was separated into male and female subjects but the other groups were not.

Data for zinc (Zn) and carbonic anhydrase (U\*) were expressed in terms of their relative quantities in

- (1) The erythrocytes in 1 cc. of whole blood
- (2) each million of red blood cells
- (3) each cc. of packed cells and
- (4) in relation to each gm. of hemoglobin

Finally, the ratio  $R = \frac{\text{Zn/cc. packed cells}}{\text{U/cc. packed cells}}$  was calculated as an index of the interdependence of the two functions investigated.

In the normal and leukemic series the number of cases allowed of an internal statistical analysis. In the remaining groups the data have been compared to the normal mean  $\pm 2\sigma$  the value which includes at least 95 per cent of the observations. The factor  $R = \frac{\text{Zn}}{\text{U}}$  was treated statistically in all five groups.

### MATERIAL

A total of 103 samples of blood obtained from 77 individuals was studied. Twenty-eight samples were obtained from 13 male and 12 female medical students and technicians who comprised the normal group. Eighteen samples from 15 subjects who had leukemia or malignant diseases of the lymphatic tissues were analyzed. Twenty-seven samples were obtained from 10 patients with pernicious anemia, 9 of these were either untreated or had been treated with liver for a very short period when first seen. Two of the former were followed for periods of from 10 to 369 days while one had been under liver maintenance therapy for one year.

Three patients had refractory anemia. Four patients had hemianemic as a consequence of hemorrhage, 2 of these patients had ceased bleeding when studied and had restored their hematological picture to normal levels. Three samples were obtained from 2 patients with sickle cell anemia. Two patients had anemia of infection, and one each had nutritional, iron deficiency and Cooley's anemia.

Four samples from 3 patients with polycythemia secondary to pulmonary fibrosis and emphysema were examined. Three other patients had polycythemia vera, one each had infectious mononucleosis, congestive failure, acute rheumatic fever, jaundice secondary to carcinoma of the head of the pancreas, hemochromatosis, cirrhosis and multiple sclerosis.

The age of the subjects in the normal and pathologic series ranged from 20 to 83 years.

### OBSERVATIONS

In normal subjects, the absolute values for zinc concentration and for carbonic anhydrase activity, and the values for these functions relative to the various hematologic measurements were within the normal range previously reported,<sup>11, 15</sup> the means and standard deviations found in the present study did not differ significantly from those of the other series.<sup>11, 15</sup> There was no difference between the sexes. The value for R for all normal subjects was  $4.1 \pm 0.98$  under the conditions of the present study, and the correlation between zinc and carbonic anhydrase levels was good (table 1, fig. 1). Actually, zinc and carbonic anhydrase measurements paralleled each other closely regardless of the presence or absence, or the nature of pathologic change (tables 1-5). The Pearson method moment coefficient

\* U = Units as defined by Altschule and Lewis

of correlation between the two measurements was 0.48 for all 103 samples, a numerical value of 0.48 represents good correlation. The ratio  $R$  varied within narrow limits close to the normal.

U = Units of carbonic anhydrase as defined by Altschule and Lewis.<sup>17</sup>

† This Unit is the mean corpuscular carbonic anhydrase.

In patients with diseases other than pernicious anemia, both the zinc and carbonic anhydrase activity of one ml. of whole blood were found to be above or below the normal level to a degree proportional to the red blood cell count and hemato-

FIG. 1—The relationship of Zn in micrograms per cc. of erythrocytes to carbonic anhydrase in U units per cc. of erythrocytes in normal subjects

The rectangle denotes the normal range. The line connecting with the zero point is drawn through the normal mean of both parameters

With reference to institution of therapy

in Case 98 (table 2, fig. 2) which was an instance of sickle cell anemia. No other cases of anemia in this group show a simultaneous deviation from the normal unit values for zinc and carbonic anhydrase content. The R value in patients with diseases other than pernicious anemia was  $3.6 \pm 0.99$ , the mean being somewhat lower than found in the normal series, but with a similar standard deviation.

The data on patients with pernicious anemia (table 3, fig. 3) show concomitant significant elevation of unit zinc concentrations and carbonic anhydrase activities in the untreated state, with both gradually returning to normal with

FIG. 3—The relationship of Zn in micrograms per cc. of erythrocytes to carbonic anhydrase in U units per cc. of erythrocytes in pernicious anemia.

The rectangle denotes the normal range. The line connecting with the zero point is drawn through the normal mean of both parameters.

effective therapy. The values for both, in 1 ml. of whole blood, are correspondingly higher than could be expected on the basis of the hematologic findings and, therefore, are normal or nearly normal in the absolute sense.

In all cases of pernicious anemia seen before or shortly after institution of therapy, the red cell zinc concentration and carbonic anhydrase activity per unit of red cells were markedly and concomitantly elevated. Under therapy, both parameters returned to normal levels (fig. 4). In Case 128, where a prolonged follow-up study was possible, there was a simultaneous return of both functions to normal on the 66th day. In the untreated cases, R is lower than normal, suggesting the possibility of a relative increase in carbonic anhydrase in relation to zinc.

It should be pointed out that in anemic blood at activities as high as the ones which these values represent, the bio-assay technic is not as reliable as it is at lower values. However, the possibility cannot be excluded that a true activation of the enzyme was present under these circumstances. The mean R value for the whole series, however, was normal.

FIG 4—Simultaneous change of Zn content and carbonic anhydrase activity in erythrocytes as a function of days under treatment in two patients with pernicious anemia

In the case of leukemic red blood cells the spread of values was considerable, as indicated by a large standard deviation (table 4, fig 5). However, the mean of both variables was within the normal range. Samples No 10-76, No 44-2, and No 63-2, showed a concomitant rise in unit zinc and U values. There was a rise in zinc, not accompanied by a rise in U in Case No 10-12. R reflects the wide range of measurements though remaining within normal limits.

There was no deviation from the normal unit values in polycythemia, the amount of zinc due to red blood cells in 1 cc of whole blood was increased, as a consequence of the increased red blood cell mass. The ratio R was within normal limits.

## DISCUSSION

The subjects of the present study on whom concomitant zinc and carbonic anhydrase determinations were carried out have been described in part in previous communications.<sup>11-13</sup> Since it was not possible to obtain simultaneous analyses in all instances in the above series, the present group is a chance sample of the two larger series.

It is clear from the data that both zinc and carbonic anhydrase are present in erythrocytes in a fixed ratio under normal circumstances, and vary simultaneously in disease. Both are independent of hemoglobin concentration, this is apparent in the data on untreated pernicious anemia, where there are normal or high zinc and carbonic anhydrase values in the face of a low hemoglobin. Under therapy, there is a relative fall in zinc and carbonic anhydrase, as opposed to a rising hemoglobin concentration.

It appears from the data that zinc and carbonic anhydrase are mutually dependent variables, their correlation being good in terms of the coefficient of correlation. Absolute correlation did not, however, occur. This may be the consequence of the large error in the method for carbonic anhydrase. Also, both measurements are not analogous, for one is a quantitative chemical technic and the other a method

FIG. 6—The relationship of Zn in micrograms per cc. of erythrocytes to carbonic anhydrase in U units per cc. of erythrocytes in miscellaneous disorders (polycythemia vera, secondary polycythemia, infectious mononucleosis, congestive failure, acute rheumatic fever, carcinoma of pancreas, hemochromatosis, cirrhosis, multiple sclerosis).

The rectangle denotes the normal range. The line connecting with the zero point is drawn through the normal mean of both parameters.

measuring biologic activity. Other limitations of the latter procedure have already been pointed out<sup>16</sup>; it should be re-emphasized, moreover, that the conditions for this bio-assay are remote from those which prevail under physiologic circumstances. Measuring the activity of the enzyme under these artificial conditions does not allow quantitative determination of enzyme concentrations. Therefore, the ratio  $R = \frac{\text{Zn/cc packed cells}}{\text{U/cc packed cells}}$  is only an arbitrary coefficient showing the existence of a functional rather than a chemical interrelation. The latter could be established only on a weight by weight basis.

It has been pointed out that the enzyme may be inactivated while retaining its original proportion of zinc. This may possibly account in part for the lack of absolute correlation which has been alluded to. Since there was an inevitable delay

between venipuncture and analysis, a certain amount of manipulation and change in temperature during transport between the two laboratories may also have increased the R value

A change in the degree of physiologic activation of the enzyme cannot be completely dismissed as the possible cause for a decrease of  $R = \frac{Zn}{U}$

Keilin and Mann's data<sup>1</sup> indicate a different zinc concentration for ox and sheep, and human carbonic anhydrase. Because of the facts pointed out above, the present data do not elucidate this point further, since the absolute quantity of enzyme per unit cells cannot be determined with any present technique

It has been suggested<sup>15-18</sup> that carbonic anhydrase deficiency may be an important etiologic factor in dyspnea. It is clear, however, that one cannot correlate with precision the loss of carbonic anhydrase with respiratory or cardiovascular symptoms because of the lack of a method for measurement of the *concentration* of the enzyme. Furthermore, the normal *in vivo* requirements to maintain normal respiratory function are not known at present. With the aid of the here established *in vivo* correlation of concentration of the metal and the activity of the enzyme system, it might become simpler to use erythrocyte zinc concentration as an index of carbonic anhydrase content in some phases of respiratory and humoral physiology

Observations made here demonstrate the occurrence in some anemias of a state of zinc deficiency in the erythrocytes, the findings of the present study indicate the functional significance of this deficiency since the latter is associated with a deficiency of carbonic anhydrase activity. This is strikingly similar to the deficiency of iron in erythrocytes, with its concomitant lowering of hemoglobin level. In addition, it is worthy of note that lack of zinc and of iron in erythrocytes commonly occur together in clinical conditions

#### SUMMARY AND CONCLUSIONS

A good correlation exists between zinc content and carbonic anhydrase activity of the red blood cells under all conditions studied, including anemia and polycythemia. In almost all patients with anemias other than pernicious anemia, both zinc and carbonic anhydrase levels were lowered in parallel fashion. These changes were proportional to decreases in hematocrit and hemoglobin levels and erythrocyte counts so that both zinc and carbonic anhydrase values per unit of RBC were in the normal range. In a few instances of anemia associated with leukemia and in one of sickle cell anemia, neither zinc content nor carbonic anhydrase activity was decreased in proportion to the anemia, in these cases the zinc and carbonic anhydrase levels per unit of blood were both elevated to the same degree.

Patients with pernicious anemia showed no decrease in absolute values for zinc and carbonic anhydrase activity in spite of marked lowering of hematocrit and hemoglobin levels and of erythrocyte count. Accordingly, both zinc concentration and carbonic anhydrase activity per unit of blood were elevated, often to a marked degree. These increases were parallel, varying inversely with the degree of anemia, when they regressed under treatment, both did so at the same rate.

There are no methods available for estimating carbonic anhydrase *concentration*; all methods now in use measure only the *activity* of the enzyme. It is suggested that zinc concentration could be used as an indicator of carbonic anhydrase content of the red blood cells.

#### ACKNOWLEDGMENTS

Drs. Joseph C. Aub and Ira T. Nathanson were kind enough to refer several patients for study. Dr. Byrl J. Kennedy was most helpful in regard to obtaining samples of blood. The technical work was performed by Miss Mary Lou Roney, Betty Hickey and Marion Taylor.

# HEINZ BODY PHENOMENON IN ERYTHROCYTES

## A REVIEW

By STEWART H WEBSTER, PH D

AMONG the early investigators of hemolytic substances were Casper and Hoppe<sup>5</sup> who in 1859 observed the brown coloration of blood due to nitrobenzene. Since then there has been a continued interest in the action of such toxic materials on the formed elements of the blood. The accelerated development of synthetic organic chemistry during the latter half of the 19th Century created numerous industrial hazards and poisons, at the same time providing the toxicologists with many new compounds with which to work. Among the coal tar products and derivatives of aniline thus produced, phenylhydrazine was of great importance because of its marked physiological action. Prepared in 1875 by Emil Fischer,<sup>25</sup> its behavior in rabbits was studied ten years later by Hoppe-Seyler,<sup>58</sup> the discoverer of methemoglobin.

### EARLY OBSERVATIONS ON MORPHOLOGIC CHANGES IN THE ERYTHROCYTES

The marked action of chlorates had attracted the attention of several workers. As early as 1882, Riess<sup>101</sup> described the presence of one or more small, generally round, globules and granules in the erythrocytes of a person poisoned by potassium chlorate. Drawings were included which showed the appearance of these particles. Somewhat later, Marchand,<sup>85</sup> who had worked on chlorate intoxication previous to this discovery of Riess,<sup>84</sup> observed similar changes in a dog poisoned with the sodium compound. Finally, Lewin<sup>82</sup> had observed the formation of granules within red cells treated *in vitro* with hydroxylamine.

One year later, Robert Heinz (1865-1924), in 1890, studying the action of phenylhydrazine and its derivatives on the blood, observed the changes seen earlier by the above workers, described them in detail, in regard to their appearance, behavior and ultimate fate, and devised a method for staining them, using a wet preparation for this purpose. Drawings were also given showing both the stained and the unstained granules in the blood of several species of animals.<sup>42</sup>

These bodies were depicted by Heinz<sup>42</sup> as round, oval or serrated granules which are very refractile and hence can easily be seen. There may be one or more within the cell wall and they may move around (Brownian motion) or remain fixed in one position. Ordinarily they are eccentrically placed, being located near the margin. Sometimes they appear to protrude from a cell, as if hanging by a stalk, and frequently they can be observed outside the cells in the plasma (schistocytes of Ehrlich). The sizes of the particles vary greatly, being 1-2 microns in diameter in rabbits, guinea pigs and dogs and much larger in cats, often amounting to a third or half of the cell diameter. Heinz recommended supravital examination of the blood, using a dilute solution of methylene blue in isotonic saline solution for staining these

From the Laboratory of Physical Biology, National Institutes of Health, Bethesda, Maryland

particles blue, hence, the term blue particles (blaukörper). This staining solution had been used earlier, in 1882, by Bizzozero<sup>2</sup> in demonstrating the presence of blood platelets.

Initially, Heinz regarded the presence of these granules as pathognomonic of poisoning by phenylhydrazine or its derivatives. However, further researches indicated a large number of substances capable of inducing similar changes. As observed by Heinz, these characteristic changes in the erythrocytes were found in one or more species of animals following administration of many organic compounds such as aniline, toluidine, toluidene diamine, nitrobenzene, dinitrobenzene, p-aminophenol, ethyl aminobenzoate (p), phenylhydrazine, acetylphenylhydrazine and phenylhydroxylamine. However, no such action was observed with benzene, phenol, phenacetin, acetanilid, antipyrine or benzyl amine, and the aliphatic amines. Among inorganic compounds, chlorates and hydroxylamine produced Heinz bodies but not hydrazine or sodium nitrite, although all four substances were very active in producing methemoglobin in vivo.

Ehrlich,<sup>19-21</sup> who at that time was an authority both on anemia and on stain technology, referred to the frequent presence of *hemoglobinemic inclusion bodies* (hämoglobininämische Innenkörper) in erythrocytes of toxic animals as well as in the blood of certain anemic persons. Dustin<sup>17</sup> pointed out that the term inclusion body is unsatisfactory since the particles often appear to be extruded from the cell. The term inner body is likewise objectionable since the particles sometimes appear to be on the surface of the erythrocyte.

Ehrlich and Lindenthal,<sup>18</sup> who found similar bodies in the blood of a person with chronic nitrobenzene poisoning, assigned priority for the discovery of the so-called inner bodies to Ehrlich. This, together with the fact that the senior author's name has been repeatedly misspelled Ehrlich in the literature, presumably has much to do with the confusion which exists even today as evidenced by the use of such numerous terms as Ehrlich-Heinz or Heinz-Ehrlich bodies, Heinz blue granules (Heinzsche Blaukörper), inclusion bodies (Innenkörper or Innenkörperchen), hemoglobinemic inner bodies, hemoglobinemic inclusion bodies, substantia metachromatica granularis,<sup>12</sup>  $\beta$ -substance and Polkörperchen.<sup>20-21</sup>

Heubner,<sup>49</sup> on the basis of Ehrlich's report of 1892,<sup>18</sup> assigned priority to Heinz for this discovery. However, due to the prominence of Ehrlich, many of his ideas prevailed. For example, Ehrlich preferred fixed and stained blood preparations rather than supravital methods. His triacid stain, developed in 1880, was relatively difficult to use, and the results were uncertain with respect to finding inclusion bodies. Heinz preferred the supravital technique but pointed out that both wet and fixed preparations should be used, in order to secure the most information.

Shortly after the initial work of Heinz a number of investigators observed similar intracythrocytic bodies during poisoning with various chemical agents. Thus the earlier findings were confirmed by A. Huber<sup>61</sup> with dinitrobenzene, by Ehrlich and Lindenthal<sup>18</sup> with nitrobenzene, by Schmauch<sup>118</sup> with pyridine, by Schwalbe and Solley<sup>119</sup> with toluidene diamine, by Winogradow<sup>123</sup> with chlorate and by von Domarus<sup>10</sup> with phenylhydrazine. However, much confusion existed in the literature during this period. Thus, Heinz bodies were sometimes identified

with Howell-Jolly bodies, Schmauch found his endoglobular bodies in normal cats, Schwalbe and Solley confused the bodies they saw with blood platelets and found similar forms in normal blood after coagulation. As pointed out by Jurgens and Schürer,<sup>71</sup> marginal bodies (Randkörper), discovered by Röhl in 1890<sup>104</sup> and subsequently rediscovered by Huber, by Schwalbe and Solley, and others, were similar to Heinz bodies in appearance and were often confused with the latter. There was also considerable discussion regarding the identity of Heinz blue granules of the wet preparations with the hemoglobinemic inner bodies seen in Ehrlich's fixed stained preparations. Finally, for many years some workers doubted the existence of Heinz bodies, regarding them as artifacts while others held them to be nuclear debris or nuclear derivatives.

#### CONTRIBUTIONS OF THE SCHOOLS OF PAPPENHEIM, SCHILLING, HEUBNER AND OTHERS

A second period in the development of knowledge regarding the Heinz bodies started about 1911 when Pappenheim and his students were attracted to this field.<sup>94</sup> Almost simultaneously Schilling and his co-workers began similar investigations. Two problems were of paramount importance in the work emanating from these two schools during the following years. The first was concerned with the chemical composition and properties of the Heinz bodies, the other had to do with the mechanism by which they were formed. These problems were so interrelated and so complex that much more data were needed than were then available. A third problem, involving the relationship between methemoglobin- and Heinz body formation, was investigated with a variety of substances by Heubner and his students.<sup>4 38 46 49 51 53 70 76 97 117 122</sup>

#### *Chemical Nature of Heinz Bodies*

Morawitz and Pratt<sup>91</sup> had found that the erythrocytes from animals poisoned by phenylhydrazine were more resistant than normal, as measured with salt solutions and various hemolytic agents. Itami and Pratt<sup>66</sup> proposed the term *pachydermia* to describe this change in resistance of the erythrocyte. They found also that the stroma sediment of anemic blood would not dissolve in water, the particles contained in the residue appearing like Heinz bodies. Sattler,<sup>108</sup> Hirschfeld<sup>86</sup> and Rosenthal<sup>106</sup> all studied the behavior of erythrocytes displaying this increased resistance without arriving at the chemical nature of such a change.

Hartwich,<sup>40</sup> working with Pappenheim, isolated Heinz bodies in large enough quantities to work with them in pure culture. From their solubility in pepsin and hydrochloric acid and from their other reactions it was concluded that the bodies contained protein and lipid material together with some iron.

Pappenheim and Suzuki<sup>95</sup> investigated the behavior of Heinz bodies with respect to their resistance toward certain hemolytic substances, as saponin. Suzuki<sup>123</sup> found that an increase in resistance occurs in blood poisoned *in vivo* by a mixture of pyroline and toluylene diamine, this increase being caused chiefly by the extremely resistant Heinz bodies rather than by a diffuse *pachydermia*.

Further investigations of the composition of these particles were carried out by

Kunkel,<sup>74</sup> who was able to show that they contained no altered hemoglobin but considerable phosphatide, some protein and cholesterol and a colored iron compound which was not identified. Hess and Müller,<sup>47</sup> by selective staining technique, demonstrated that the Heinz particles gave reactions for lipid material.

Heuer<sup>55</sup> drew conclusions somewhat different in that he believed the Heinz bodies to contain neither phosphorus nor phosphoprotein. Later Warburg et al.<sup>119</sup> showed that Heinz bodies produced by phenylhydrazine agreed in behavior and properties with that of denatured globin. More recently, Horecker<sup>59, 60</sup> confirmed this work, using xylydine as the substance for producing the Heinz bodies.<sup>127</sup>

By means of the electron microscope, Jung<sup>68, 69</sup> was able to follow the growth of the Heinz bodies from submicroscopic particles to those attaining half the diameter of the red cells. In the case of dinitroglycol, Heinz bodies were recognizable<sup>66</sup> after a few minutes. Evidence was also obtained that these bodies were at or in the outer surface of the erythrocyte. However, it was found that the structure of the Heinz bodies produced by various hemolytic agents was not identical in all cases. Based on these results and upon their own work, Kiese and Seipelt<sup>73</sup> were led to believe that Heinz bodies contained denatured proteins derived from the erythrocyte membrane.

Finally, as Dustin<sup>17</sup> has pointed out, in the absence of recent comprehensive studies very little can be said with certainty regarding the chemical composition of these particles except that they undoubtedly contain protein material.

#### *Mechanism of Heinz Body Formation*

The formation of Heinz bodies has been explained in a variety of ways, most of which are included in five principal mechanisms.

1 *Protoplasmic theory* Heinz conceived of the blue granules, which were later called by his name, as produced by partial necrosis of the erythrocytic protoplasm. Ehrlich believed these particles to be identical with his hemoglobinemic inclusion bodies, the latter being regarded as containing hemoglobin in a resistant form, either as methemoglobin or as altered hemoglobin. This hypothesis was in agreement with the observation that as the inclusion bodies became larger and more dense, the hemoglobin in the cells appeared to become paler and often disappeared. Since these abnormal structures were produced by substances which simultaneously produced methemoglobin, it was natural to assume that the bodies contained some form of blood pigment. This was supported by the observation that although they were basophilic before fixation, the particles became acidophilic after fixation occurred. However, the work of Kunkel<sup>74</sup> and of Hartwich,<sup>40</sup> in showing that Heinz bodies contain neither hemoglobin nor methemoglobin, appears to dispose of this protoplasmic theory. The observed acidophilic behavior is explained by Gutstein and Wallbach<sup>36</sup> as due to the lipid content of these particles rather than to their hemoglobin content, as believed by Ehrlich.

2 *Nuclear theory* The early attempt to relate Heinz bodies and nuclear remains, such as Howell-Jolly bodies, met with little success. The latter show intense basophilia after fixation while Heinz bodies do not. Zadek and Burg<sup>126</sup> held that no confusion existed in identifying these particles although Schilling<sup>118</sup> maintained that he had observed a transition between these two forms. Cats appear to be the

species giving the greatest difficulty in experimental work since the blood of young animals often contains Howell-Jolly bodies.<sup>26</sup> According to Schilling,<sup>116</sup> part of the Schmauch inner bodies of cats are Howell-Jolly bodies and part are Heinz bodies. Gross and associates<sup>23</sup> have reported that the latter are found regularly in normal animals of this species.

3 *Pre-existent theory* Two forms of this theory were advanced, the first of which was given by Schwalbe and Solley<sup>119</sup> who identified Heinz bodies with platelets. They thought that there existed within a normal red blood cell a structure similar to that of the Heinz body, the latter being liberated and appearing as a platelet in the plasma. Aside from shape, refractile properties and occurrence in the plasma, these bodies have nothing in common.

The other form of the theory was derived from the work of Schilling<sup>13 57 109-111 114</sup> who conceived of the normal erythrocyte as having a very complex structure similar to a nucleated cell. He advanced the idea that the Heinz body is a pathogenically produced form of the capsule body normally present. These capsule bodies are not observable except by special histologic and staining technic, whereas the Heinz bodies are frequently visible even in unstained preparations. This theory was also supported by the experimental investigations of Deutsch.<sup>7</sup>

Gutstein and Wallbach,<sup>36-37</sup> although agreeing in general with the pre-existent theory of Schilling, differed somewhat in details. They held to the pre-existence in normal erythrocytes of both *Innenkörper* and *Innenkörperchen*, the latter corresponding to the *Kapsulkörper* of Schilling and the former to the *Glas-körper* of Schilling. It is the *Innenkörperchen* which are the pre-existing forms of the Heinz bodies. Gutstein and Wallbach reached these conclusions also through special staining techniques which they regarded as superior to those of Schilling.

Since the special technic used to produce these structures in normal erythrocytes require somewhat severe and rough processes great artifacts may result. For this reason, Dustin<sup>17</sup> rejected this pre-existent theory.

4 *Reticulo-filamentous theory* The basophilic nature of the Heinz bodies and of the reticulocytes suggested a relationship between them. However, it is known that on supravital treatment basic stains, such as brilliant cresyl blue, precipitate material existing normally in reticulocytes in a diffuse form so that it becomes visible. On the other hand, under similar conditions the stain does not alter Heinz bodies which, if large enough, can be seen in an unstained condition. Restaining of the supravital preparation, following fixation with methyl alcohol, will color the reticulocytes but not the Heinz bodies to any marked extent, according to Dustin.<sup>17</sup>

The two kinds of bodies can be further differentiated by a study of their occurrence, Heinz bodies being found usually, though not invariably, in mature erythrocytes and rarely in the young cells (reticulocytes). Freifeld, Schilowa and Ludwinsky<sup>6</sup> have demonstrated the lack of correlation between reticulocytosis and the number of Heinz bodies present in the blood stream of poisoned animals.

5 *Detritation theory* The theory most widely held at the present time favors the view that Heinz bodies are newly formed particles generally found in mature erythrocytes and formed from them in the course of an irreversible reaction with the toxic agent or with some intermediate metabolite formed therefrom. Heub-

ner<sup>49 52</sup> and Dustin<sup>17</sup> held that these particles are derived from the erythrocytic protoplasm which suffers injury. However, investigations by Jung<sup>68 69</sup> with the electron microscope support the contention<sup>22 3</sup> that the particles are denatured proteins derived from the cell membrane. It is difficult to reconcile the latter view with the frequently observed phenomenon of Brownian movement of the Heinz particles in wet blood preparations<sup>45 121</sup>. It is quite possible that during the preparation of the blood cells for photography with the electron microscope, marked changes occur in the structure of the Heinz bodies.

Finally, it is not known for certainty where the Heinz bodies are formed. However, the fact that they can be produced *in vitro* is regarded by Moeschlin<sup>11</sup> as strong evidence of their peripheral origin.

### *Methemoglobin Formation and Heinz Bodies*

Most of the early workers assumed that there was a close connection between the formation of Heinz bodies and the formation of methemoglobin. However, in 1911 Friedstein<sup>77</sup> showed that no direct relation existed between the two. This was confirmed later by Heubner and his students<sup>4 38 46 49 50 70 78 97 117 122</sup> with many different hemolytic substances. Moeschlin<sup>88</sup> reported finding Heinz bodies in white mice treated subcutaneously or orally with sodium nitrite, although Pulina<sup>97</sup> was unable to confirm this. Following oral administration of sodium nitrite in food, Richardson<sup>99</sup> found in white Swiss mice Heinz bodies in most of the erythrocytes and also cyanosis and methemoglobinemia. On the contrary, Gutstein and Wallbach<sup>36</sup> were able to produce Heinz bodies in mice by injection of Nile blue sulfate without the formation of methemoglobin. Webster, Liljgren and Zimmer<sup>131</sup> have demonstrated in similar fashion that Heinz bodies can be produced in 75-100 per cent of the erythrocytes of mice by administration of sulfanilamide without the formation of appreciable amounts of this same blood pigment.

Goodman and Gilman<sup>37</sup> offered as a probable explanation of the action of phenylhydrazine on the erythrocyte the splitting of the hemoglobin into heme and globin, at least a portion of the remaining hemoglobin being catalyzed by the globin to form methemoglobin and perhaps other unidentified substances.

Heubner,<sup>40</sup> however, regarded the action as an opening of the tetrapyrrole ring of hemoglobin, the toxic material or some derivative thereof being able to modify the globin which was precipitated as a Heinz body and acquired an affinity for basic stains.

The presence of other blood pigment derivatives, formed in many cases along with Heinz bodies and methemoglobin, has been studied by Heubner,<sup>49 50 51</sup> by Jung,<sup>67 68</sup> and by Kiess<sup>72 73</sup> and associates. These pigments, known as verdoglobins, appear to have different spectral characteristics according to the substances producing them.<sup>72</sup> The constitution of one of the most important of these blood pigments, sulfhemoglobin (called also verdoglobin S) is unknown. Heubner and his school<sup>40</sup> believe that it contains no sulfur but this view is not widely held.<sup>39</sup> Lemberg and associates<sup>80</sup> remarked about the confused state of knowledge concerning the chemical nature of sulfhemoglobin.

Heubner<sup>50 51</sup> and Kiese and Seipelt<sup>72</sup> held that the occurrence of Heinz bodies,

methemoglobin and verdoglobin were three separate and independent phenomena, although they frequently occurred simultaneously. Kiese and Seipelt,<sup>72</sup> studying the effect of certain hemolytic substances on the blood of dogs and rats, found that Heinz bodies occurred whenever verdoglobin was present. This was explained by assuming that those substances which were toxic to the hemoglobin and converted it into verdoglobin, were also toxic to the membrane of the erythrocyte, thus denaturing it more or less completely and forming one or more Heinz bodies. Simultaneous formation of Heinz bodies and methemoglobin was explained in the same way. Heubner<sup>52</sup> attributed the nonuniform behavior of certain substances, with respect to these three phenomena, to different compounds produced during the course of intermediate metabolism of these substances.

Species differences may play an important role. For example, it is well known that it is difficult to produce methemoglobin in rabbits but not in cats,<sup>48, 81</sup> this pigment regularly occurring in the blood of normal cats.<sup>66</sup> Again, Richardson<sup>99</sup> has shown that it is difficult to produce methemoglobin in mice using sulfanilamide, sulfhemoglobin being formed much more easily. However, the reverse is true for chickens. Similar species differences have been shown by the inability of Kunz<sup>75</sup> to produce Heinz bodies in guinea pigs with m-dinitrobenzene, whereas they were readily produced by Bredow and Jung,<sup>4</sup> using cats as experimental subjects. Likewise, negative results were obtained with sulfapyridine by Moeschlin and Hurschler<sup>90</sup> when rabbits were used but mice gave positive findings. It is evident, therefore, that negative results with rabbits or guinea pigs, for example, should not be interpreted as meaning that a given substance cannot produce Heinz bodies in other species or in man. Since Heinz bodies and anemia have been shown to occur with little or no production of methemoglobin, care should therefore be taken in drawing conclusions either from the presence or absence of granules and/or altered blood pigment.

#### *Role of the Spleen in Heinz Body Phenomenon*

During the existence of Heinz bodies in experimental animals there frequently occur also secondary signs of hemolytic anemia, such as anisocytosis, polychromatophilia, and reticulocytosis. In addition, there is often evidence of splenomegaly.<sup>17</sup>

The role of the spleen in Heinz body phenomenon has been of interest ever since the primary observations of Heinz.<sup>44</sup> Hess and Muller<sup>47</sup> showed that in the macrophages of the spleen of rats poisoned by pyridine were found large numbers of Heinz body phagocytes. However, the blood leaving the spleen by the splenic vein contained no Heinz bodies and they concluded that the particles collected within the sinuses were the cause of the observed swelling. Schilling<sup>11</sup> had noted the increase in Heinz bodies of an antifebrin poisoned dog following splenectomy and Zadek and Burg<sup>128</sup> confirmed these experimental observations on several patients. Schilling<sup>11</sup> likewise observed the presence of Heinz bodies in splenectomized normal animals, i.e., those not made toxic by any Heinz body-producing material. It therefore appears as if splenectomy were a predisposing factor in the formation of Heinz bodies.<sup>16</sup>

It is difficult to reconcile this filtering action of the spleen with the experimental

observations on the persistence of Heinz bodies in the blood stream following discontinuance of the toxic material. Thus, with pyrodine, Cruz<sup>6</sup> found that the length of time required for Heinz bodies to disappear ranged from 8-9 days for rabbits to 9-18 days for dogs. Webster, Liljegren and Zimmer<sup>131</sup> observed Heinz bodies in a guinea pig for 11 days following a single exposure to stibine,  $SbH_3$ , in a rat for 33 days and in mice for 55 days after similar exposures.

Further work on the relationship between Heinz body occurrence and the action of the spleen, using various species of normal and splenectomized animals and various hemolytic substances, appears to be necessary in order to extend our knowledge of the role played by the spleen in hemolytic anemias produced by chemical agents.

### STAINING CHARACTERISTICS OF HEINZ BODIES

Enough has been mentioned to indicate that while Heinz preferred wet preparations stained with methyl violet, Ehrlich preferred fixed and stained smears. Advocates of both methods are well represented in the literature.

#### *Supravital Staining*

Friedstein,<sup>27</sup> working with Pappenheim, investigated the vital staining properties of Heinz bodies with a considerable number of basic dyes, such as brilliant cresyl blue, methyl violet, toluidine blue, azur I, malachite green, neutral red and Nile blue sulfate. The latter was regarded as being the quickest, *most intense* and easiest to use of those studied. The author found that after fixation the Heinz bodies had practically no affinity for basic stains but showed an attraction for acid stains.

Since Nile blue sulfate is but slightly soluble in water an alcoholic solution is usually used, allowing a thin film to form on a slide by evaporation. The blood is then smeared out on top of the dried film, the slide being allowed to stand in a moist chamber for 5-7 minutes before examining the cells. This is the usual Pappenheim-Schilling technic of supravital examination. A common modification of this method<sup>8</sup> consists of placing a drop of blood directly on the dried film of Nile blue sulfate and covering with a cover slip.

Gutstein and Wallbach<sup>36</sup> claimed to be able to stain both fixed and unfixed preparations by either basic or acid dyes. In their supravital staining technic, they mixed the fresh blood with aqueous solutions ( $\frac{1}{2}$ -1 per cent) of the stain and observed it between slide and cover slip.

Webster, Liljegren and Zimmer,<sup>130</sup> investigating the staining of Heinz bodies, found methyl violet and gentian violet superior to Nile blue sulfate since these violet dyes were easily soluble in water and in Locke's solution, the latter being modified so as to be more nearly isotonic with the blood to be examined.

Friedstein<sup>7</sup> confirmed Heinz's observations<sup>13</sup> that Heinz bodies could be detected in supravital preparations much earlier in the course of an intoxication than they could be detected in stained smears. Observations in this laboratory<sup>131</sup> have shown that the initial formation of Heinz bodies, when these particles are very small, can best be recognized in wet preparations, where the cells are moving and

rolling over. Since the cells are subjected to the least trauma in the wet preparations, estimation of the number of Heinz particles can be made most accurately in this way.

### *Staining of Fixed Smears*

Ehrlich's triacid stain did not prove to be very satisfactory for use in staining Heinz bodies and many other technics were devised. Panoptic staining (May-Grunwald-Giemsa) after fixation is not very satisfactory since the Heinz particles are not markedly stained. Recently,<sup>130</sup> a method has been developed utilizing the scheme of simultaneously fixing and staining the smear with a solution of methyl violet in ethyl alcohol.

Smears have the advantage of giving permanent records but the mechanical trauma during preparation of the slides frequently lead to removal of many of the Heinz bodies from the cells, as can be readily seen on inspection of the thinnest portions of the slide.

### *Heinz Bodies in Thick Drops*

Basing his work upon a technic of Ross,<sup>107</sup> Schilling<sup>112, 118, 116</sup> made extensive use of thick drop preparations, the drops after drying being hemolyzed and stained with Giemsa solution. This process has the disadvantage that the cells are largely removed so that estimation of the number of Heinz bodies in the cells is not possible. However, Schilling<sup>112</sup> regarded this method as demonstrating the presence of Heinz bodies with certainty.

### *Differential Methods*

Zadek and Burg<sup>136</sup> and Dustin<sup>17</sup> summarized the differential staining characteristics of basophilic particles, Howell-Jolly bodies, reticulocytes and Heinz bodies. The latter author cautioned also against confusion between Heinz bodies and other types of granules. Friefeld, Schilowa and Ludwinowsky<sup>38</sup> warned against confusing the marginal bodies (Randkörper) of Röhl with Heinz bodies and Jürgens and Schurer<sup>71</sup> showed how these could be distinguished. Nizer<sup>92</sup> advocated use of dark field examination as well as special staining technics for distinguishing between Heinz bodies, reticulocytes and basophilic particles. Fertman and Doan<sup>21, 22</sup> showed that Heinz bodies did not give the reactions for iron shown by siderocytes<sup>11, 34</sup> so that the two kinds of particles could be differentiated.

## EXPERIMENTAL PRODUCTION OF HEINZ BODIES

### *Production in Vitro*

Friedstein<sup>77</sup> held that Heinz bodies are formed only *in vivo*, the toxic material and the blood *in vitro* forming only methemoglobin. This was the opinion of most investigators during the first quarter of this Century. *In vitro* formation of these particles was not found by Strampelli<sup>122</sup> with pyrodine nor by Lambrechts, Nizer and Khady,<sup>6, 78</sup> with sulfonamides. The observation by Lewin<sup>4</sup> in 1889 of the formation of granules within erythrocytes by the *in vitro* action of hydroxylamine appears to have gone unnoticed. However, beginning in 1930, it was shown

by Waddell, Wolff and Lanou,<sup>18</sup> by Bratley, Burroughs, Hamilton and Kern<sup>5</sup> and by Cruz<sup>6</sup> that Heinz bodies can be produced in erythrocytes in vitro by means of acetylphenylhydrazine Moeschlin,<sup>89</sup> Nizet,<sup>92</sup> Lambrechts, Nizet and Khady<sup>76</sup> and Gajdos and Tiprez<sup>78</sup> likewise obtained positive results with phenylhydrazine. In vitro production of Heinz bodies by certain sulfonamides was reported by Moeschlin<sup>89</sup> and by Jürgens and Schürer,<sup>71</sup> although this could not be confirmed by Lambrechts and associates.<sup>78</sup> Willi<sup>122</sup> observed Heinz body formation in vitro with a preparation of guaiacol and Gross and associates<sup>92</sup> found similar action with dinitroglycol. More recently, Webster, Liljegren and Zimmer<sup>121</sup> have demonstrated this action with mouse blood for a number of hemolytic agents, using supravital staining technic.

Therefore, it can no longer be held that these morphologic changes within erythrocytes are restricted to action taking place in the living body. However, it appears that the conditions necessary for the development of Heinz bodies are much more favorable in vivo than in vitro.

#### *Production in Vivo*

Among the series of aromatic compounds which were found to produce Heinz bodies when administered to animals, the best known examples are phenylhydrazine and the acetyl derivative, pyrodine. These two drugs remained favorites, either used alone or in connection with toluenediamine, in which the acetyl compound is quite soluble, as a means of producing and studying Heinz bodies in experimental animals. However, the extremely toxic nature of these substances caused systemic effects which were undesirable.

Richardson<sup>98-100</sup> demonstrated in 1940-41 that Heinz bodies could be produced in white Swiss mice following oral administration of sulfanilamide, sulfapyridine, sulfathiazole, sulfanilylguanidine, and sodium nitrite. Using mice, positive results with nitrite were reported by Moeschlin<sup>88</sup> but this was not confirmed by Pulina.<sup>97</sup>

Renewed interest in Heinz bodies began in 1940 following the discovery by Moeschlin<sup>87</sup> of these particles in the blood of a number of persons treated with sulfapyridine. Comparison of this drug, one of the first of the sulfonamides to be used clinically, was carried out with sulfathiazole<sup>88</sup> and other derivatives.<sup>90</sup> Moeschlin and his associates found that sulfanilamide produced the greatest number of Heinz bodies and sulfathiazole the least. Since the response of rabbits to these compounds was very slight, white mice were used as experimental animals. Similar work was carried out by Hirschler<sup>61</sup> and by Lambrechts and associates.<sup>77</sup> The occasional failure to produce Heinz bodies may have been partly due to differences in modes of administration of the toxic substances and also to species differences.

Following the work of Moeschlin, Heubner and his students investigated the formation of Heinz bodies in experimental animals after the administration of a number of industrially important aromatic compounds and nitro compounds, such as nitroaniline, nitrobenzenes, nitrotoluenes, nitroglycerin and nitroglycols.<sup>4</sup>

Recently, Figge<sup>23</sup> showed that these altered erythrocytes could be easily and quickly produced in mice by the administration of sulfanilamide in their drinking water. Such a technic has been used<sup>121</sup> as a means of studying Heinz body formation for many months without the severe systemic effects produced by hydrazine derivatives.

The chemical constitution of the substances capable of producing these marked changes in erythrocytes has long been of interest. With the exceptions of chlorates and hydroxylamine, only compounds belonging to the aromatic series and containing nitrogen have been included until recently. Dustin<sup>17</sup> believes that the action by chlorates is quite different from that of other substances producing Heinz bodies. If this be accepted, it would seem that nitrogen in the form of amino or nitro groups associated with a benzene nucleus was potentially capable of inducing changes in the erythrocytes. That this is true for a variety of substituted hydrazine compounds can be seen from the work of Hueper<sup>63</sup> and of Von Oettingen and Deichmann-Gruebler.<sup>126</sup> Von Oettingen's summary<sup>125</sup> of the action of aromatic amino and nitro compounds likewise suggests the possibility of similar action with many of these industrially important substances.

In the original work by Heinz, this investigator examined the blood of the experimental animals for Heinz bodies about 24 hours following the administration of the toxic material. Recently, Gross, Bock and Hellrung,<sup>22</sup> working with cats, have shown the rapid formation of these particles. Within 10 minutes after subcutaneous injection of dinitroglycol, 100 per cent of the erythrocytes in the peripheral blood were found to contain one or more refractile particles.

Jung<sup>69</sup> has mentioned that arsine is capable of forming Heinz bodies, and Figge<sup>24</sup> has indicated that they can be formed by such varied substances as cobalt, paraminobenzoic acid and acetalilide.

Work in this laboratory<sup>131</sup> has shown that a number of other substances are also capable of inducing Heinz body formation. Among those investigated, positive results were obtained with arsine, stibine (antimony hydride), sodium nitrate and sodium nitrite besides several others used in earlier studies.

From these results it is evident that our knowledge of the relationship between chemical constitution and Heinz body formation is quite fragmentary and there exists a great need for fundamental investigations in this field.

#### *Estimation of Number of Heinz Bodies in Erythrocytes*

Since the Heinz bodies are not hemolyzed by water or saponin solution, these particles remain suspended in the solution or they can be thrown down in a centrifuge. When suspended they cause a turbidity which frequently interferes with hemoglobin determinations or counting of white cells, since in the latter case they are insoluble in acetic acid. Cruz<sup>6</sup> made use of this turbidity in quantitatively estimating the amount of Heinz bodies present. This method was also followed by Horecker<sup>19, 60</sup> and by Pimenta de Mello.<sup>98</sup> Such measurements, however, do not give the actual number of particles or the percentage of erythrocytes containing such particles. For such determinations counting may be done on fixed stained

smears<sup>120</sup> or on supravital preparations.<sup>121</sup> The latter method has the advantage that even the smaller Heinz bodies can be seen and thus the beginning stages of the phenomenon can be detected and followed.

#### CLINICAL OBSERVATIONS AND USE OF HEMOLYTIC SUBSTANCES

It should be recalled that the first observations of refractile bodies in erythrocytes were made on persons poisoned by chlorates. Ehrlich likewise observed them in certain cases of anemia and Ehrlich and Lindenthal found them in a person suffering from chronic nitrobenzene poisoning.

Following Hoppe-Seyler's work in 1885,<sup>58</sup> phenylhydrazine was extensively used as a chemical for producing experimental anemia in animals but it was not until 1918 that it was introduced by Eppinger and Kloss<sup>20</sup> for the treatment of polycythemia rubra vera. Since then it has received extensive clinical application. However, the use of this drug was attended by some danger and less toxic derivatives were sought. The acetyl compound, prepared by Liebreich,<sup>59</sup> was introduced in a somewhat impure form in England in 1887 by Dreschfeld<sup>14, 15</sup> under the name pyrodine, not for reducing the red cell count but as an antipyretic agent. Its high toxicity, which in rabbits was shown to produce jaundice and hemoglobinemia, led to its disuse until it was introduced in 1926-28 by Stone and co-workers<sup>121</sup> and by Bassett and co-workers<sup>1</sup> for the symptomatic treatment of polycythemia vera.

Little interest in Heinz bodies has been shown in this country, particularly with reference to clinical studies. This was pointed out by Cruz<sup>6</sup> and by Pimenta de Mello,<sup>96</sup> following a search of the literature on phenylhydrazine and pyrodine, and more recently by Fertman and Doan.<sup>77</sup> Almost all references to Heinz body occurrence in human blood are found in the German literature.

Schilling,<sup>112, 115</sup> who reported finding Heinz bodies in children poisoned from aniline, coined the term *Innenkörperanämien* to designate those illnesses in which the presence of inner bodies was regularly found in the erythrocytes of the circulating blood.

The discovery of Moeschlin<sup>87</sup> in 1940 that certain sulfonamides were capable of producing Heinz bodies in human beings stimulated other investigators to look for morphologic changes in the erythrocytes in their hematologic examinations. From the work of Heubner and his students, who have shown that a large number of substances are capable of producing Heinz bodies in animals, it is evident that more attention should be paid to this phenomenon in persons exposed to these substances in industry. As early as 1941, directions<sup>8</sup> were given for the microscopic examination of blood for Heinz bodies in German munition workers. In this country examination of TNT workers by Sievers et al.<sup>120</sup> indicated the need for further investigations of this phenomenon. Moreover, Gross, Bock and Hellrung<sup>23</sup> recommended that examination for Heinz bodies be made routinely in munitions plants, at least in cases of suspected poisoning, since such examinations require only a few moments and the simplest equipment. The supravital method of examination,<sup>121</sup> requiring only a drop of fresh blood, can quickly reveal even minute Heinz bodies, if present. This is in contrast to the determination of methemo-

TABLE I — *Summary of Chief Clinical Reports of Heinz Bodies in Man*

Author	Date	Diagnosis
Ricss <sup>101-103</sup>	1882-1908	Potassium chlorate poisoning
Heinz <sup>41</sup>	1890a	Pyrodiac poisoning
Ehrlich <sup>19</sup>	1892	Anemia
Ehrlich and Landeorthal <sup>18</sup>	1896	Chronic nitrobenzene poisoning
O Hnber <sup>82</sup>	1912	Potassium chlorate poisoning
Schullio <sup>112 113 115</sup>	1921 1927 1928	Chronic anisefebrio poisoning, anisef poison ing malaria blackwater fever
Zadek and Burg <sup>126</sup>	1930	Chronic myelogenous leukemia, cryptic hy- perchromic anemia, anisef poisoning
Geokin and Raschewskaja <sup>29</sup>	1933	Anisef poisoning
Freifeld Schilova and Lud vovowsky <sup>36</sup>	1937	Poisoning by anisef, dinitrobenzene and dinitrotoluene
Uogrecht <sup>104</sup>	1938	Cryogenice (phenylsemicarbazide) poisoning
Moerschlio <sup>87</sup>	1940	Sulfapyridine poisoning
Rohr <sup>105</sup>	1940	Nitrobenzene poisoning
Doenog <sup>9</sup>	1941	Dimethylenediammonodiphenylsulfone poison- ing
Dustio <sup>16</sup>	1941	Colchicine poisoning
Willi <sup>122</sup>	1942	Acetol (guanacol) poisoning
Pimcota de Mello <sup>86</sup>	1945	Polycythemia vera treated with pyrodiac
Sievers et al <sup>120</sup>	1945	Trinitrotoluene poisoning
Fertmao and Doao <sup>81 21</sup>	1945 1948	Inclusion body anemia (following use of erythrol tetramate)
Willi <sup>124</sup>	1947	Elloxan (Sulfanilamino-dimethyl pyrim- idine) poisoning

globin, which requires expensive special equipment for accurate evaluation. Moreover, indications of methemoglobin cannot be used as a criterion of the presence of Heinz bodies.

Finally, table 1 lists the chief clinical reports of Heinz bodies found in man.

## SUMMARY

Certain morphologic changes in the erythrocytes, first described accurately by Heinz in 1890, have been noted by many investigators both in experimental animals and in man. These Heinz bodies, called by various names, appear to be newly formed particles originating either from the protoplasm or the membrane of the red blood cells in the course of irreversible injury by a toxic agent. The chemical nature of these particles is uncertain but they appear to consist largely of denatured proteins. They may occur in the blood in the absence of methemoglobin or sulf hemoglobin and without anemia, these phenomena being independent of each others. Removal of these bodies from the blood stream is frequently accomplished by their destruction in the spleen, often with resulting increase in size of this organ.

From the staining characteristics of Heinz bodies it is usually possible to distinguish them from other similar particles and to measure them quantitatively. Little is known of the relationship of chemical constitution of toxic substances to Heinz body formation. The indications are that some inorganic substances are capable of inducing this action as well as many aromatic nitro and amino compounds.

The presence in the blood stream of significant amounts of Heinz bodies is evidence of some injury to the erythrocytes. If this injury is severe it may lead to marked hemolysis and anemia.

Clinical cases of Heinz body occurrence in man, due either to drugs or to industrial poisoning, are cited and the need for further work and especially for Heinz body evaluation in routine hematologic examinations is pointed out. A bibliography is included in this review of the literature covering the chief contributions to work on Heinz bodies.

# STUDIES ON THE DESTRUCTION OF RED BLOOD CELLS

## V IRREVERSIBLY SICKLED ERYTHROCYTES THEIR EXPERIMENTAL PRODUCTION IN VITRO

By SHU CHU SHEN, M D , ELEANOR M FLEMING, A B AND W B CASTLE, M D

IT IS well known that in fresh preparations of the blood of patients with sickle cell anemia the erythrocytes can be sickled immediately by displacement of the oxygen from the hemoglobin, for example, by carbon dioxide or by nitrogen. These sickled cells can be no less rapidly restored to their normal form when the blood is reexposed to oxygen. However, even in stained smears of the peripheral blood of some of these patients a few sickled cells may be present, despite the inevitable exposure of the film of fresh blood to atmospheric oxygen.<sup>1-3</sup> These cells, then, differ from the majority of the sickled erythrocytes artificially produced in fresh preparations in that they have somehow acquired an inability to revert to the normal discoidal form upon exposure to oxygen. Moreover, though crescentic or elliptic, these cells do not display filamentous extremities as do freshly sickled erythrocytes in wet preparations.<sup>2, 4-6</sup>

Although in patients with sickle cell disease the majority of the erythrocytes when exposed to a range of hypotonic concentrations of sodium chloride exhibit a so-called increased osmotic resistance, critical study of the phenomenon indicates that in certain patients a small percentage of the erythrocytes may actually possess a slightly decreased osmotic resistance relative to the normal range, that is, they are hemolyzed in concentrations of sodium chloride, somewhat more concentrated than those which initiate the osmotic lysis of normal blood. Because it is possible to cause any type of red cell so far studied to acquire decreased resistance to osmotic lysis by sterile incubation in vitro,<sup>7</sup> the question arose as to whether they irreversibly sickled erythrocytes and those erythrocytes with decreased resistance to osmotic lysis are in fact the same cells. It also appeared to be possible that both characteristics were the result of the same process, namely, stagnation of the red cells in vivo in the tissue capillaries.<sup>3, 7, 8</sup> Accordingly, the peripheral bloods of 4 patients with sickle cell disease were studied with respect to the natural presence of irreversibly sickled erythrocytes and as to their artificial production in vitro.

### METHODS

The conventional characteristics of the formed elements of the peripheral blood were determined by the usual methods. The percentages of irreversibly sickled erythrocytes in samples of capillary or of defibrinated venous blood following exposure to air or to 90 per cent oxygen and 10 per cent carbon dioxide in a tonometer were determined while counting 1,000 or more red cells in blood films prepared

From the Thorndike Memorial Laboratory Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine Harvard Medical School Boston Mass  
This investigation was aided in part by a grant from the John and Mary R. Markle Foundation

and treated with Wright's stain in the usual manner. The percentages of reticulocytes were also determined in blood spread upon coverslips previously prepared with a dried film of brilliant cresyl blue. Thereafter the dried blood films were counterstained with Wright's stain and the number of reticulocytes determined by counting 1,000 or more red blood cells.

In order to observe the effect of sterile incubation at 37.5°C. for 24 hours *in vitro* on the reversibility of the sickling phenomenon, 7 cc. samples of sterile defibrinated blood were equilibrated in 250 cc. tonometers with gas mixtures containing either 90 per cent oxygen and 10 per cent carbon dioxide or 90 per cent nitrogen and 10 per cent carbon dioxide. Each tonometer, which was equipped with a long glass capillary pipet inserted through a hole in a rubber stopper closing the open end, was sterilized prior to each experiment. With the tonometer lying on its side on a table with the stopcock open, the apparatus was carefully rotated back and forth about its long axis usually during three periods of 3 minutes each, separated by short intervals. During each of these periods the gas mixture, which was stored in a cylinder equipped with a reducing valve, after bubbling through water, was allowed to flow freely through appropriate rubber tube connections to the capillary pipet and so into and through the tonometer. The stopcock and the inflow tubing were then closed. During a 24-hour period in an air incubator the blood in the tonometers was reequilibrated three or four times with the same gas mixture. At the end of the incubation period the blood in the tonometers was again carefully equilibrated with whichever of the two gas mixtures was required by the experimental procedure, in the same fashion as in the beginning.

Whenever a sample of blood was to be removed for study, the tonometer was held in a vertical position. The long glass capillary pipet, which then dipped beneath the surface of the blood, was operated as a bulb pipet and a small amount of blood was sucked into it and so removed from the tonometer without contact with room air. After withdrawal from the tonometer, the tip of the pipet was inserted beneath the surface of a sterile pool, on the surface of a glass slide, composed of two drops of a 40 per cent formalin solution diluted 10 times by volume with physiologic salt solution.<sup>9</sup> A drop of blood was then expelled and immediately mixed with the formalin solution. From this mixture as well as directly from other drops of blood expelled from the pipet without contact of its tip with coverslips, blood smears were prepared using either plain coverslips or coverslips previously filmed with brilliant cresyl blue. If the experiment was to continue, the remaining blood was expelled from the pipet which was then reinserted in the tonometer with appropriate sterile precautions. The blood remaining in the tonometer was then equilibrated twice with the appropriate gas mixture as described above and the apparatus was returned to the incubator. Later the blood films were treated with Wright's stain in the usual manner and the percentages of sickled erythrocytes and of sickled reticulocytes were determined.

## RESULTS

As shown in table 1, sickled red cells persisted in the blood of 3 of the 4 patients, Cases 2, 3, and 4, after exposure of capillary or defibrinated venous blood to atmos-

phoric air or even after the further equilibration of the latter with a gas mixture consisting of 90 per cent oxygen and 10 per cent carbon dioxide. In Cases 3 and 4, the number of sickled erythrocytes differed strikingly at the time of the two observations made on each patient's blood. As noted by others,<sup>2, 4-8</sup> these irreversibly sickled cells, although exhibiting the sickle or oat shaped form in fixed as well as in wet preparations, did not possess the filaments which are seen in wet preparations of blood artificially sickled by exposure to nitrogen or to carbon dioxide gas.

TABLE 1.—Percentages of Irreversibly Sickled Erythrocytes in Peripheral Blood of 4 Patients with Sickleemia

Case Number	Capillary Blood	Venous blood	
		De fibrinated in air	De fibrinated and oxygenated

4	2.69	46	12.2	9.0	22.4	79.6	33.2	26.4	7	0.47	0.34	0.26	0.18	0.14
Normal										0.43	0.40	0.39	0.36	0.33

\* 15.6 grams of hemoglobin are considered to be 100 per cent.

In table 2 are shown the peripheral blood values including the data on quantitative osmotic fragility studies on the blood of the 4 patients. It will be noted that in the blood of Case 1 a portion of the red cells were more susceptible than are normal cells to lysis by hypotonic salt solution although no irreversibly sickled erythrocytes were seen in the blood films from this patient. Thus in Case 1, 1 per cent of the red cells were hemolyzed in 0.58 per cent NaCl instead of, as in the normal individual, in 0.43 per cent NaCl. In Cases 2, 3, and 4, on the other hand, 1 per cent of the red cells were hemolyzed in 0.38, 0.44, and 0.47 per cent NaCl respectively, and thus like the rest of the red cells of all of the patients, were less susceptible than are normal red cells to lysis by hypotonic solutions.

In an attempt to modify the capacity of the red cells for change in shape, sickling

of the erythrocytes was prevented as far as possible during sterile incubation of blood samples for 24 hours in equilibrium with a gas phase containing 90 per cent oxygen and 10 per cent carbon dioxide. As shown in table 3, experiment C, these erythrocytes almost completely lost their capacity to become sickled upon subsequent reduction of the hemoglobin by exposure to 90 per cent nitrogen and 10 per cent carbon dioxide. Likewise, except in Case 3 where the effect was only partial, the erythrocytes which were kept sickled in the nitrogen-carbon dioxide atmosphere during the incubation period largely lost their ability to reassume the dis-

TABLE 3—Percentages of Sickled Erythrocytes in Blood Samples from 4 Patients with Sickleemia following Incubation for 24 Hours in the Presence and Absence of Oxygen Respectively

\* Figures in column are percentages of sickled reticulocytes in terms of total reticulocytes

( ) Figures in parentheses are the results of observations using the formalin technic.

coidal form upon exposure to the oxygen-carbon dioxide gas mixture (experiment F). In table 3 are also shown the immediate effects of equilibration with the oxygen-carbon dioxide gas mixture (experiment A) and with the nitrogen-carbon dioxide gas mixture (experiment D). Also included are the results of the various experimental procedures upon the reticulated erythrocytes of Cases 3 and 4. The prolonged incubation in the oxygen-carbon dioxide gas mixture appeared effectively to prevent the subsequent sickling of the reticulocytes upon exposure to a nitrogen-carbon dioxide gas mixture (compare experiment C with experiment D).

However, incubation in the nitrogen-carbon dioxide gas mixture was not as effective in rendering reticulocytes irreversibly sickled when subsequently exposed to oxygen as it was in the case of the nonreticulated erythrocytes (compare experiment E with experiment F). The figures obtained with the formalin technic are shown in parentheses in table 3. The percentages of sickled erythrocytes in the smears prepared from the formalin solution agreed reasonably well with those made in the usual fashion. The technic could not be employed for reticulocytes, which were rendered unable to take the brilliant cresyl blue stain by previous exposure to formalin.

### DISCUSSION

The fact that the sickling of the erythrocytes strikingly increases the viscosity<sup>7</sup> of the blood provides an obvious explanation of the characteristic pathologic lesions of sickle cell disease, namely, the congestion of the capillaries and the multiple thromboses and infarcts including frequently the total atrophy of the spleen.<sup>2, 7, 8</sup> However, many sickled red cells apparently traverse these areas of lowered oxygen tension and thus with proper precautions against exposure to air are demonstrable in wet preparations of venous blood. The readiness with which these cells revert to the discoidal form distinguishes them from the irreversibly sickled erythrocytes which may also be present in such wet preparations and which form the subject of this communication. Only the irreversibly sickled forms, however, are observed in the usual stained blood films. The hypothesis examined experimentally here is that the persistently sickled form has been assumed because of prolonged or repeated intermittent exposure to anoxia and consequent erythrocytosis in the capillaries of various organs.<sup>2, 7, 8</sup> Janet Watson<sup>6</sup> infers the effectiveness of stagnation *in vivo* from the finding of Diggs and Bibb of irreversibly sickled forms in the pleural or ascitic fluids of patients whose peripheral blood showed none of these forms. Clearly, from the experiments reported here, the effect of sterile incubation *in vitro* upon erythrocytes maintained in the sickled form under anoxic conditions is to cause loss of ability to revert to the discoidal form upon reexposure to oxygen. Moreover, these incubated sickled erythrocytes resemble the irreversibly sickled forms seen in fixed blood smears with respect to their lack of the hairlike processes frequently extending from the ends of the crescents that are characteristic of the sickled forms artificially produced in wet preparations by exposure to nitrogen-carbon dioxide gas mixtures.<sup>2, 4-6</sup>

Although irreversibly sickled reticulocytes are rarely seen in the peripheral blood of patients with sickle cell disease,<sup>1-3, 6</sup> these cells are capable of sickling *in vitro* if their hemoglobin is sufficiently reduced.<sup>1, 2, 6</sup> The present experiments indicate that after incubation in the nitrogen-carbon dioxide gas mixture a larger proportion of the reticulated than of the nonreticulated erythrocytes, especially in the blood of Case 4, were able to revert to the discoidal form upon re-exposure to oxygen. This finding confirms the suggestion already made by others<sup>3, 6</sup> that the acquisition of a permanently sickled form requires that the red cell receive a sufficiently long or repeated exposure to whatever bodily processes are concerned in order to allow for maturation of the reticulocyte to the more adult form. However,

although the blood of Case 1 showed an increased osmotic fragility of a small proportion of the red cells, a finding which conceivably could be due to erythro-stasis *in vivo*,<sup>7</sup> no irreversibly sickled red cells were present. The fact that irreversibly sickled reticulocytes are so rarely seen in the peripheral blood is strong evidence against the possibility that they are young cells recently delivered by the bone marrow.

It may be argued that exposure to atmospheric oxygen in the preparation of the blood films would invalidate the experiments in which formalin fixation was not used. However, reversal of sickling due to exposure to atmospheric oxygen would be expected only in the case of films made from blood removed from the tonometer after equilibration with the nitrogen-carbon dioxide gas mixture, as, for example, in experiments C, D, and E of table 3. The differences between the numbers of sickled red cells in the ordinary smears and in the formalin fixed smears do not significantly alter the conclusions drawn from these experiments.

### CONCLUSIONS

1 The peripheral blood of patients with sicklemia when examined in wet preparations without contact with air may contain two distinct types of sickled erythrocytes.

The first type, which exhibits filamentous processes extending from the ends of the crescentic forms, resembles those produced by exposure of the blood to nitrogen or to carbon dioxide gas *in vitro*. Exposure to oxygen causes these red cells to revert to the discoidal form.

The second type appears as sickle or oat shaped forms without filaments, in fixed as well as in wet preparations of the blood, and does not revert to the discoidal form upon exposure to oxygen. Such red cells rarely exhibit the vital staining properties of reticulocytes. In the blood of one patient their presence did not correlate with the presence of red cells of relatively increased osmotic fragility.

2 When samples of the blood of 4 patients with sicklemia were incubated for 24 hours at 37.5°C in the absence of oxygen, the nonreticulated red cells largely lost their ability to resume the discoidal form when exposed again to oxygen. To a considerable extent, however, reticulocytes retained their ability to revert to the discoidal form. Similar incubation in the presence of oxygen caused loss of the ability of both adult and reticulated red cells to sickle when subsequently deprived of oxygen.

3 These studies confirm the hypothesis that sufficient intermittent or continuous stagnation of the red cells in various organs *in vivo* with consequent sickling may result in the production of irreversibly sickled forms.

4 The fact that reticulocytes do not as readily acquire the property of becoming irreversibly sickled after incubation *in vitro* as do nonreticulated red cells may explain the fact that irreversibly sickled reticulocytes are rarely seen in stained blood films.

## OVALOCYTOSIS ASSOCIATED WITH THE SICKLE CELL TRAIT

By ROBERT S FADEM, M D

THE PATIENT described in this report is a young Negro male whose blood showed both ovalocytosis and sickling. Only one other instance of the coexistence of ovalocytosis and the sickling phenomenon has been found in the literature.<sup>8</sup> In that instance some of the ovalocytic cells became sickled in fresh sealed blood preparations. In the patient reported here it was found that only the discoid red blood cells were capable of sickling, the ovalocytes did not undergo this change.

Ovalocytosis has been reported in both sexes and in both white and Negro races.<sup>11-13</sup> The precursors of the oval shaped cells show no detectable morphologic abnormality, and the anomaly apparently first makes its appearance in the reticulocyte stage.<sup>17</sup> The factors which determine the unusual shape of these cells have not been established.

It has been suggested that ovalocytosis is hereditary and is transmitted as a simple mendelian dominant<sup>6,7</sup> Entire families with the trait have been studied.<sup>1,2,4,12</sup> It has also been suggested that (a) these cells represent a structural adaptation to some unknown constitutional factor<sup>10</sup>, (b) that they have an intraerythrocytic susceptibility to some extraerythrocytic influence, either one of which, or both, may be congenital.<sup>7</sup>

Several different observations have been made upon ovalocytes in fresh sealed preparations. One case has been described in which the ovalocytes became more round in appearance when sealed for long periods of time in fresh preparations.<sup>12</sup> Other cases have been reported in which the ovalocytes did not change shape in such preparations.<sup>3, 5</sup> One case has been reported in which some of the ovalocytic cells became sickled in such preparations.<sup>8</sup>

We wish to report in this paper a patient observed during routine hematologic study who presented the peripheral blood picture of ovalocytosis associated with the sickle cell trait. Sickling was observed to occur only in the normal appearing discoid red blood cells.

## CASE REPORT

(Hospital File # 345974) W J 25 year old Negro male entered the San Diego Naval Hospital with the complaints of intermittent chest pain bone aches and weakness of approximately three months duration. He had been seen by his private physician on three occasions prior to his admission to the hospital. At each visit the patient was told he had an anemia (because of the unusual appearance of his red blood cells). Treatment with iron and multiple vitamins was instituted at each visit. As the patient was a government employee he was admitted to the San Diego Naval Hospital for a thorough examination on July 21 1947.

The physical examination was entirely normal. On routine hematologic studies his peripheral blood was observed to contain 76 per cent ovalocytes. Because of this observation further studies were made that revealed the data shown in tables 1, 2, and 3.

Fresh wet preparations under cover glass sealed with vaselin<sup>®</sup> showed sickling of the normal appearing discoid red cells within 18 hours. The ovalocytes did not change their shape after 72 hours in the same preparations (see fig. 3).

Manuscript prepared while author was a medical officer in the United States Navy

## OVALOCYTOSIS AND THE SICKLE CELL TRAIT

FIG 1 —PHOTOMICROGRAPHS OF PERIPHERAL BLOOD MADE IN THE USUAL MANNER AND STAINED WITH WRIGHT'S STAIN  $\times 600$

FIG. 2.—REPRODUCTION OF A PHOTOMICROGRAPH OF CELLS AS SEEN AFTER IMMEDIATE FIXATION OF PERIPHERAL BLOOD WITHDRAWN UNDER OIL.  $\times 950$

Bone marrow examination revealed a normal bone marrow. The red blood cell precursors were all of normal shape. There was no evidence of hyperplasia of the red blood cell elements.

The patient's symptoms disappeared after he was told he had no serious blood disease. He was discharged on the fifth hospital day completely asymptomatic. He was seen again six months after discharge on January 20, 1948, at which time blood studies were essentially unchanged from admission studies.

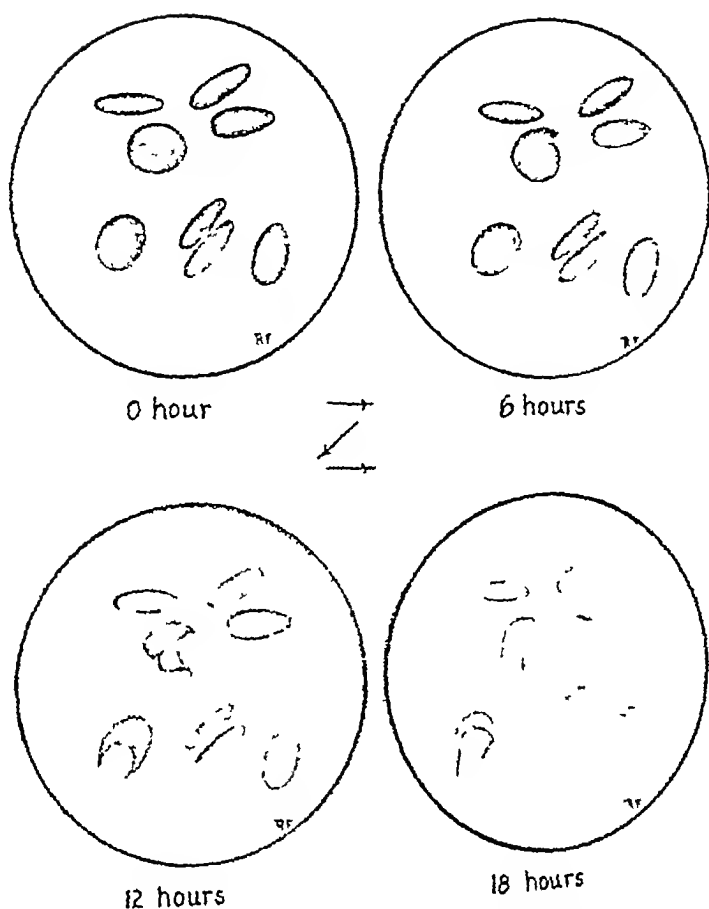

FIG. 3—FRESH FIXED PREPARATION SHOWING SICKLING OF NORMAL APPEARING DISCOID CELLS. Drawings made at 0, 6, 12 and 18 hours. Ovalocytes showed no sickling.

#### SUMMARY

1. A patient has been presented whose circulating red blood cells were composed of 65-84 per cent ovalocytes, 3-11 per cent sickled cells, and some normal appearing discoid cells.
2. The red blood cell counts and the blood indices were within normal limitations.
3. The red blood cells showed an increased resistance to hypotonic saline solutions.

	<i>per cu mm</i>	<i>per cu mm</i>	<i>Gms per 100 cc</i>	<i>%</i>	<i>cu <math>\mu</math></i>	<i>micro micrograms</i>	<i>%</i>
8-22-47	7,500	4.7	14	41	87	30	34
8-25-47	8,200	4.9	14.5	42	86	30	34
8-27-48	7,250	4.9	14.5	42	86	30	34

\* figured to the nearest whole number

TABLE 2

Date	Fresh Fixed Preparation*		Fresh Sealed Preparation at 72 hours	
	Ovalocytes	Sickled Cells	Ovalocytes	Sickled Cells
	<i>%</i>	<i>%</i>	<i>%</i>	<i>%</i>
8-22-47	76	8	75	16
8-25-47	84	3	84	14
8-27-47	65	11	67	21

\* To determine the exact percentages of ovalocytes and sickled cells circulating in the peripheral blood at any one time blood was withdrawn from a vein into a syringe under oil directly into a ten per cent formalin in saline fixing solution. The fixed cells were then placed on glass slides, the fixing solution allowed to evaporate and the cells stained with Wright's stain<sup>8</sup>

TABLE 3

Date	Fragility Tests		
	Subject	Hemolysis began	Hemolysis completed
8-22-47	Control	40	32
	Patient	32	28
8-27-47	Control	42	36
	Patient	38	30

4 The peripheral blood showed a daily variation in the percentage of circulating ovalocytes, from 65 per cent to 84 per cent, and in the percentage of circulating sickle cells, from 3 per cent to 11 per cent

5 After 72 hours in fresh wet preparations the per cent of ovalocytes remained essentially unchanged from that of fresh fixed blood

6 The percentage of sickled cells was found to be increased after 18, 24, and 72 hours in fresh wet preparations as compared to the percentage of sickled cells found in fresh fixed preparations

7 Some of the normal appearing discoid red blood cells were observed to sickle in fresh wet preparations within 18 hours

#### CONCLUSION

We have shown that this patient's red blood cells demonstrated the condition referred to as ovalocytosis. In addition, the patient's normal appearing discoid

red blood cells demonstrated the sickling phenomenon when observed in fresh sealed wet preparations. Therefore, we wish to present this patient as one whose peripheral blood showed the result of two different abnormalities one, ovalocytosis, and the other, the sickle cell trait.

# THE BLOOD AND BONE MARROW IN PATIENTS WITH CIRRHOSIS OF THE LIVER

By LAWRENCE BERMAN, M D , ARNOLD R. AXELROD, M D , THOMAS N. HORAN, M D , SAMUEL D. JACOBSON, M D , ELWOOD A. SHARP, M D , AND ELMORE C. VONDERHEIDE, M D

## INTRODUCTION

A RELATIONSHIP between hematologic changes and cirrhosis of the liver has been shown experimentally<sup>25 27 28</sup> and clinically<sup>71 81 94</sup>. Many other-wise excellent studies are not completely satisfactory because the diagnoses of hepatic cirrhosis have not been verified by biopsy. The advantages of biopsy in the diagnosis of hepatic diseases have been emphasized and illustrated by Hofbauer, Evans and Watson,<sup>39</sup> and others.<sup>19 39 49 56 28-28</sup>

## CASES AND METHODS

This study is based on a review of the literature and analysis of 25 cases with diagnoses of hepatic cirrhosis verified by biopsy of the liver. Complete blood studies with simultaneous aspiration biopsy of sternal marrow obtained within one-half to twenty-four hours before the liver specimen was removed were carried out on all patients. There were 19 males, and 6 females. The age range of the patients was 31 to 71 years, 76 per cent ranged between 43 and 68 years. The case histories, clinical and pathologic diagnoses are given in the appended case reports.

Peripheral blood studies, including determinations of volumetric data and corpuscular constants were carried out according to methods described by Wintrobe.<sup>22</sup> Normal ranges for erythrocyte, leukocyte and platelet counts, mean corpuscular volume, and mean corpuscular hemoglobin referred to are those stated by Wintrobe and found to be in agreement with observations made in our laboratory. Differential counts of cells in the bone marrow were based on enumeration of a minimum of 2000 cells. Serum protein levels were determined by the method described by Osgood.<sup>64</sup>

The hematologic terminology used by us follows that in current use by Downey<sup>24</sup> and Jones.<sup>44</sup>

Liver specimens were obtained peritoneoscopically. The evaluation of the liver lesion was based chiefly on the degree of fibrosis and atrophy according to the following schedule: Grade I cirrhosis, traces of fibrosis; Grade II cirrhosis, definite fibrosis plus atrophy of hepatic cells; Grade III cirrhosis, fibrous tissue equal to hepatic parenchyma; Grade IV cirrhosis, fibrous tissue exceeds hepatic parenchyma. In addition, other factors such as fatty metamorphosis, lymphocytic infiltration, and atypical bile duct or hepatic cell regeneration were taken into consideration.

From the Departments of Pathology and Medicine, Wayne University College of Medicine, and the City of Detroit Receiving Hospital. Technical assistance was furnished by the Anemia Laboratory, Outpatient Department, Harper Hospital.

The degree of hemosiderosis was determined by examination of sections stained for iron

The sternal marrow was obtained and processed by the methods described by two of us (L B and A R A) <sup>8</sup> Estimations of megakaryocyte content of marrow samples were based on counts of megakaryocytes in serial sections of aspirated marrow particles Fifty consecutive fields outlined by the Whipple eye piece disc were examined at 100 micron intervals The total numbers of megakaryocytes in the fifty fields were compared with similar counts on material from 10 healthy individuals

All studies were made shortly after admission of the patients to the hospital, before various therapeutic measures were undertaken

## THE BLOOD PICTURE IN PATIENTS WITH CIRRHOSIS OF THE LIVER

### Literature

*Anemia* The common occurrence of anemia in patients with cirrhosis of the liver has been mentioned frequently <sup>1 2 13 14 27 32 33</sup> The presence of anemia is not considered to be dependent on bleeding <sup>2 27-28 46</sup> It has been stated that the anemia is usually either macrocytic or normocytic, it is not hypochromic unless hemorrhage is a complicating factor <sup>31</sup> Wintrobe<sup>32</sup> noted that while macrocytic anemia is found in cases of liver disease of various types, and is most common in cirrhosis, the anemia is present only in instances of disease of long duration and wide extent. The reported frequencies of macrocytosis, macrocytic or hyperchromic anemia vary greatly For example Benhamou<sup>4</sup> observed macrocytic anemia in only 11 per cent of 35 patients, whereas Rosenberg and Walters<sup>71</sup> found that macrocytosis, almost invariably associated with anemia, was present in 89.7 per cent of 48 patients Others<sup>1 15 33</sup> have reported incidences from 43 to 91 per cent. Some of the inconsistency in the reports may be due to inadequacy of determining cell size without the use of data obtained with the hematocrit

The anemia of cirrhosis may also be normochromic or normocytic.<sup>8</sup> In a group of patients reported by Fellinger and Klima <sup>27 32</sup> 5 per cent of 40 patients had normochromic anemia Anderson and Strandell<sup>2</sup> reported normochromic anemia in 48 per cent of 61 patients who did not have bleeding from the gastrointestinal tract Although bleeding is not an essential factor in the pathogenesis of hyperchromic or normochromic anemia in patients with hepatic cirrhosis, it is usually a prominent cause for microcytic hypochromic anemia <sup>1 2 4 27 32</sup>

A significant number of patients do not have appreciable anemia When bleeding is carefully excluded as has been done in the two reports by Fellinger and Klima <sup>27 32</sup> 34 per cent of patients in various stages of the disease are free of anemia The dictum that anemia in cirrhosis is proportional to the duration and extent of the disease as is true in experimental animals,<sup>37</sup> does not seem to be substantiated by our review of the literature

*Qualitative Changes in Erythrocytes* With regard to qualitative changes in erythrocytes in the anemic patients the literature presents conflicting views According to Whitby and Britton<sup>41</sup> there is a generalized macrocytosis without gross anisocytosis or poikilocytosis Alessandrini et al.<sup>1</sup> described a characteristic isomacrocytosis while others<sup>4 26</sup> emphasized the prominence of increased anisocytosis We have observed increased anisocytosis and poikilocytosis in some of our patients but these features were neither present nor absent with sufficient regularity to be of value for distinguishing between the macrocytic anemia of cirrhosis and that of other conditions

*Leukocytes* There are few detailed reports of the leukocytic picture in patients with cirrhosis of the liver Some authors<sup>1 24 46 73 76 93</sup> were unable to find characteristic changes in the leukocytes Others<sup>29 32 46</sup> have discussed the occurrence of leukopenia especially in uncomplicated cases <sup>27 33</sup> It is generally recognized that some patients exhibit a normal leukocyte count while others experience leukocytosis after paracentesis, surgical operations or infections Masio<sup>42</sup> felt that the appearance of coarse azurophilic granules in increased numbers in the majority of monocytes is a pathognomonic sign of cirrhosis of the liver Saragea and Seicaresco<sup>75 76</sup> stated that even in leukopenic cases there is a high

percentage of neutrophils. The latter statement implies that lymphopenia may be partly or largely responsible for the leukopenias.

**Platelets.** Occasional references to the platelet counts<sup>1 28 40 46 74</sup> include few with particular emphasis on platelets. The counts were subnormal in a varying proportion of cases. Monges, Poinso and Fructus<sup>59</sup> made a special study of platelets in 15 patients. In 12 there was thrombocytopenia of moderate degree. Morlock and Hall<sup>61</sup> found thrombocytopenia in 17.5 per cent of 80 patients. A hemorrhagic tendency was present in many of their patients regardless of the presence or absence of low platelet counts, but it was relatively twice as frequent when thrombocytopenia was associated.

### *Results of the Present Study*

**Anemia.** Our cases were analyzed for the presence or absence of anemia, and the characteristics of the anemia, when present. Twenty-one patients (84 per cent) had anemia. Sixteen of the anemic patients exhibited macrocytosis, 3 had normocytosis, and 2 had microcytosis. Approximately three-fourths of our patients had macrocytic anemia or macrocytosis on their initial studies. In 84 per cent of the cases with macrocytic anemia the mean corpuscular hemoglobin values were normal or elevated. Microcytic hypochromic anemia was associated with chronic and acute blood loss from the gastrointestinal tract in 1 of 2 patients with this type of anemia.

TABLE 1—Erythrocyte counts and grade of cirrhosis in 25 patients

Grade of cirrhosis	Number of cases	Range RBC (per cu mm)	Average RBC (per cu mm)
1	5	2,450,000-4,020,000	3,530,000
2	9	2,750,000-5,000,000	4,068,000
3	4	2,790,000-3,870,000	3,393,000
4	7	2,590,000-4,950,000	3,700,600

There was no correlation between the severity of the anemia and the grade of cirrhosis (table 1).

**Leukocytes.** The total leukocyte counts ranged between 1,960 and 47,200 per cubic millimeter. Five patients had counts below 5,000, 10 had counts within the normal range (5,000 to 10,000), and 10 had leukocytosis. We did not observe a relationship between the total leukocyte counts and the presence or absence of ascites or bleeding, since leukopenia, leukocytosis and normal counts were present in both these categories. However, leukocytosis occurred with greater frequency among patients with fever or infection, or both. In other words, the presence of cirrhosis did not inhibit the leukocytic response to infection or toxemia. The severity of the liver lesion was not a factor affecting the total leukocyte counts.

In sixteen of the 25 patients (64 per cent) there was absolute lymphopenia (less than 1,500 lymphocytes per cubic millimeter). This was present regardless of whether the total counts were depressed, normal, or elevated (table 2). In fact, several of the lowest absolute counts of lymphocytes occurred in patients with leukocytosis. With the exception of 2 cases, one of which was that of a patient with both cirrhosis and chronic lymphatic leukemia, the absolute counts of lymphocytes were at low normal or lower than normal levels. Absolute lymphopenia was the most constant significant alteration in the leukocytic picture in patients with hepatic cirrhosis.

A special study was made of the peripheral blood smears in an effort to discover morphologic changes in the leukocytes of our patients. Except for occasional instances in which toxic changes of neutrophils and monocytes were seen, there were no significant alterations of the morphology of the cells.

TABLE 2.—Total leukocyte counts, absolute counts of lymphocytes and types of leukocyte picture in 25 patients with cirrhosis of the liver

Case	Total leukocytes (per cu mm)	Lymphocytes (per cu mm)	Remarks	
1	5,500	1,710	Neutropenia	
2	5,300	1,060		Lymphopenia
3	11,000	880	Neutrophilia	Lymphopenia
4	12,500	2,500	Neutrophilia	
5	6,650	1,930		
6	6,500	910		Lymphopenia
7	8,500	1,360	Neutrophilia	Lymphopenia
8	7,650	1,960		
9	3,350	670	Neutropenia	Lymphopenia
10	4,950	540		Lymphopenia
11	10,450	1,150	Neutrophilia	Lymphopenia
12	11,350	680	Neutrophilia	Lymphopenia
13	7,550	1,660		
14	23,300	930	Neutrophilia	Lymphopenia
15	4,850	580		Lymphopenia
16	10,500	1,360	Neutrophilia	Lymphopenia
17	24,500	980	Neutrophilia	Lymphopenia
18	10,800	2,710	Neutrophilia	
19	8,000	2,320		
20	12,050	3,380	Neutrophilia	
21	13,950	1,120	Neutrophilia	Lymphopenia
22	47,200	9,920	Neutrophilia	Lymphocytosis*
23	3,800	990	Neutropenia	Lymphopenia
24	5,900	1,480		Lymphopenia
25	3,200	930	Neutropenia,	Lymphopenia

\* Case 22 complicated by chronic lymphatic leukemia.

TABLE 3.—The platelet counts in 25 patients with cirrhosis of the liver

Platelets (per cu mm)	No. of cases
Less than 50,000	2
50,000 to 100,000	3
100,000 to 150,000	8
150,000 to 300,000	11
300,000 to 400,000	1

**Platelets** The platelet counts observed in our patients are shown in table 3. The counts were determined indirectly by comparing the number of erythrocytes with that of the platelets in stained blood smears. In our hands, the method yields

normal values ranging from 150,000 to 350,000 per cubic millimeter. The counts were in the low normal range or significantly lowered in 13 of 25 patients.

### *Discussion of the Peripheral Blood Findings*

We may summarize the available information regarding the peripheral blood findings in patients with cirrhosis of the liver as follows:

1. Anemia, usually of macrocytic or normocytic type, is of common occurrence.
2. In the majority of instances of macrocytosis, the mean corpuscular hemoglobin values are normal or elevated.
3. Bleeding is not an essential factor in the production of macrocytic or normocytic anemia in cirrhosis.
4. Microcytic hypochromic anemia is suggestive of chronic bleeding when it occurs in patients with cirrhosis of the liver.
5. The severity of anemia is not proportional to the duration or extent of the liver lesion, although this appears to be true of experimental cirrhosis of the liver in rats.
6. There are no constant significant qualitative changes in the erythrocytes or leukocytes.

7. In uncomplicated cases, leukopenia is likely, but the presence of cirrhosis does not prevent the leukocytic response to infection or other complications.

8. Lymphopenia, regardless of the total leukocyte count, is the most constant significant change in the leukocytic picture in patients with cirrhosis. This point seems to have been overlooked. In Masina's data on 20 patients with the disease the total leukocyte counts ranged from 3,200 to 8,360 per cubic millimeter.<sup>55</sup> The absolute counts of lymphocytes were less than 1,500 in 17 of his cases (85 per cent). Russo<sup>74</sup> supplied data on 14 patients with total leukocyte counts from 3,000 to 16,000. In ten cases (71 per cent) the lymphocytes were below 1,500 per cubic millimeter and, in an additional case, the lymphocyte count was 1,564.

9. The platelet count is in the low normal range or significantly lowered in the majority of patients. Those with severe liver damage had lower counts, on the average, than was the case for patients with slight liver damage in our material. Hemorrhagic phenomena are approximately twice as frequent in patients with thrombocytopenia as compared with patients having normal platelet levels.

The pathogenesis of anemia in cirrhosis of the liver is obscure. While it is clear that microcytic hypochromic anemia can be attributed to chronic blood loss in nearly all instances, our material indicates that normocytic or macrocytic anemias are not dependent on bleeding, as has also been shown by others.<sup>2, 27-29</sup> "It has been shown that some patients with cirrhosis of the liver have greatly increased plasma volumes."<sup>28</sup> The importance of hemodilution as a factor resulting in depressed erythrocyte levels needs further evaluation.

Various theories concerning the cause of macrocytosis have been offered. Among them are (1) Defective storage or metabolism of the anti-pernicious anemia principle (Wintrobe,<sup>22</sup> Wintrobe and Shumacker<sup>24</sup>), (2) Increased incidence of reticulocytes (which are larger than mature cells) (Rosenberg and Walters<sup>71</sup>), (3) Swelling of erythrocytes as a result of direct action of retained bile derivatives in

the peripheral blood (Meulengracht<sup>57</sup>) None of these theories is satisfactory for the following reasons (1) The hematopoietic factor has been demonstrated in the livers of patients dying of extensive hepatic disease,<sup>77</sup> (2) Marked macrocytosis may be present without marked reticulocytosis (see our cases 5, 6 and 12), (3) The degree of icterus is not proportional to the degree of macrocytosis and, as Boros<sup>18</sup> pointed out, not only is the cell volume increased but also the hemoglobin content and color index is elevated, which would not be the case if a plasma factor had caused simple swelling of the erythrocytes

It cannot be denied, however, that increased hemolysis may play a role This view is based on the observations of Watson<sup>80</sup> who cited 8 patients with macrocytic hemolytic anemia and cirrhosis of the liver, and those of others<sup>1</sup> who have utilized quantitative determinations of urobilinogen excretion in addition to complete blood studies

It is of interest that both lymphopenia and hyperglobulinemia occurred in the majority of our patients This combination recalls the work of Dougherty and White<sup>82</sup> who have demonstrated the relationship between pituitary adrenal cortical secretion on the one hand, and lymphopenia and hyperglobulinemia on the other It has also been shown that many kinds of stimuli can cause the adrenal cortical activation which results in this combination of phenomena Among them are administration of large doses of estrogens In view of the work of Glass, Edmonson and Soll<sup>82</sup> which reveals increased excretion of free estrogens by patients with cirrhosis of the liver as a result of failure of the damaged liver to inactivate estrogens, the possibility exists that the lymphopenia and hyperglobulinemia so often seen in patients with cirrhosis, in part at least, have their origin in adrenal cortical activation

## THE BONE MARROW PICTURE IN PATIENTS WITH CIRRHOSIS OF THE LIVER

### *Literature*

Reports of bone marrow can be divided into two groups those based on autopsy material and those based on aspiration of marrow from the living patient

*Autopsy Material* In most instances the marrow was studied by means of gross inspection, or by examination of sections prepared from various bones<sup>12 14 22 24-28 30 32 33 34 36 38 40 42 44 46 48 50 52 54 56 58 60 62 64 66 68 70 72 74 76 78 80 82 84 86 88 90 92 94 96 98 100 102 104 106 108 110 112 114 116 118 120 122 124 126 128 130 132 134 136 138 140 142 144 146 148 150 152 154 156 158 160 162 164 166 168 170 172 174 176 178 180 182 184 186 188 190 192 194 196 198 200 202 204 206 208 210 212 214 216 218 220 222 224 226 228 230 232 234 236 238 240 242 244 246 248 250 252 254 256 258 260 262 264 266 268 270 272 274 276 278 280 282 284 286 288 290 292 294 296 298 300 302 304 306 308 310 312 314 316 318 320 322 324 326 328 330 332 334 336 338 340 342 344 346 348 350 352 354 356 358 360 362 364 366 368 370 372 374 376 378 380 382 384 386 388 390 392 394 396 398 400 402 404 406 408 410 412 414 416 418 420 422 424 426 428 430 432 434 436 438 440 442 444 446 448 450 452 454 456 458 460 462 464 466 468 470 472 474 476 478 480 482 484 486 488 490 492 494 496 498 500 502 504 506 508 510 512 514 516 518 520 522 524 526 528 530 532 534 536 538 540 542 544 546 548 550 552 554 556 558 560 562 564 566 568 570 572 574 576 578 580 582 584 586 588 590 592 594 596 598 600 602 604 606 608 610 612 614 616 618 620 622 624 626 628 630 632 634 636 638 640 642 644 646 648 650 652 654 656 658 660 662 664 666 668 670 672 674 676 678 680 682 684 686 688 690 692 694 696 698 700 702 704 706 708 710 712 714 716 718 720 722 724 726 728 730 732 734 736 738 740 742 744 746 748 750 752 754 756 758 760 762 764 766 768 770 772 774 776 778 780 782 784 786 788 790 792 794 796 798 800 802 804 806 808 810 812 814 816 818 820 822 824 826 828 830 832 834 836 838 840 842 844 846 848 850 852 854 856 858 860 862 864 866 868 870 872 874 876 878 880 882 884 886 888 890 892 894 896 898 900 902 904 906 908 910 912 914 916 918 920 922 924 926 928 930 932 934 936 938 940 942 944 946 948 950 952 954 956 958 960 962 964 966 968 970 972 974 976 978 980 982 984 986 988 990 992 994 996 998 1000</sup> The obvious advantage of autopsy material is that the diagnoses of hepatic cirrhosis can be accepted as verified On the other hand, sectioned material obtained after death is less suitable for differentiation of marrow cells than is the case for marrow in the form of freshly prepared imprints or smears Autolytic changes which develop rapidly after death preclude accurate identification of many of the cells of the marrow<sup>70</sup> However, the distribution of cellular marrow can be observed and in fresh tissue, it is possible to distinguish the main varieties of leukocytoid and erythroid cells

Various authors have described extension of hematopoietic marrow into the shafts of the femurs,<sup>14 22 24-28 30 32 33 34 36 38 40 42 44 46 48 50 52 54 56 58 60 62 64 66 68 70 72 74 76 78 80 82 84 Rossier<sup>72</sup> who described an occasional myeloblastic reaction in addition to the usual erythropoietic reaction in his autopsy series, called attention to the fact that autopsy material is not satisfactory for identification of cells and that it was probable that the so-called myeloblasts represented erythropoietic elements Fellingner and Alima<sup>77</sup>

studied a group of 48 patients with Laennec's cirrhosis. In each case occult and gross bleeding from the gastrointestinal tract had been carefully excluded. In the autopsied cases they found red marrow in the shafts of the femurs even in the absence of bleeding.

**Biopsy Material.** The advantages of aspiration biopsy of the sternum are that the bone marrow can be examined during life before autolytic changes have occurred, the time of aspiration can be selected to coincide with the liver biopsy, the identification of cells can be made with relative ease and in addition that material for sectioning is obtainable for use in estimating the cellularity, fat content, and frequency of certain irregularly distributed cell types such as megakaryocytes.<sup>8, 8, 9</sup> In nearly all instances, investigations utilizing biopsy material have been based on the technic of sternal aspiration. The experimental work of Stasney and Higgins<sup>82</sup> was based on fresh autopsy material from rats. Since these authors prepared dry films in addition to sections of bone marrow, their observations can be compared with those of others using similar preparations from patients.

Schulten<sup>79</sup> was of the opinion that there are marrow changes in all cases of hepatic cirrhosis. Although Isaacs<sup>41</sup> described both hypocellular and hypercellular marrows in 8 patients, the preponderance of reports implies a regular appearance of cellular or hypercellular bone marrow during life.<sup>1, 4, 8, 29, 47, 50, 81, 84</sup>

**Fat Content of Marrow.** The relative fat content of aspirated marrow in cirrhosis has not been studied sufficiently. Klima<sup>47</sup> stated that although the cellularity of the sternal marrow is markedly increased, the fat content may be considerable. In one patient in whom two simultaneous sternal aspirations were done, Pizzolato and Stasney<sup>84</sup> found relative fat volumes of 1 and 3 per cent.

**Cell Content of Marrow.** The average myeloid-erythroid volume (ME volume) that is the average relative volume occupied by nucleated cells in aspirated centrifuged sternal marrow in 20 patients with hepatic cirrhosis was found to be 13 per cent by Limarzi et al.<sup>81</sup> This was considered about twice the normal value. In an additional case reported by others<sup>88</sup> the ME volumes were 5 and 10 per cent in marrow from two different sites in the sternum.

**Myeloid-erythroid Ratios.** A number of reports<sup>1, 8, 29, 51, 68-71, 81, 82</sup> include data concerning the myeloid-erythroid ratios (ME ratios) which represent the relative frequencies of myeloid leukocytes and erythroblasts<sup>8</sup> in the aspirated specimens of marrow. In some cases we have calculated the ratios from the authors' data. The combined statistics from a total of 39 cases yield ME ratios ranging from less than 1:1 to 6:1. The ME ratio was 1:1 or less in 14 cases, 2:1 to 3:1 in 23 cases, and over 4:1 in 2 cases. Benhamon and Nouch<sup>18</sup> mentioned a reversal of the ME ratio so that erythroblasts predominated, as was also observed by Limarzi and co-workers.<sup>81</sup> A similar reversal of the ME ratio indicating relative increase of erythropoiesis has been noted in experimental cirrhosis of the liver in rats.<sup>82</sup> The opinion that erythroblastic hyperplasia occurs frequently in patients with hepatic cirrhosis is upheld by additional observations on biopsy material.<sup>1, 3, 4, 29, 31, 36, 47, 50, 63, 68, 81</sup> The presence of erythroblastic hyperplasia is not dependent on bleeding.<sup>79</sup>

**Differential Distribution of Erythroblasts.** A few studies have been concerned with the differential distribution of erythroblasts. It is difficult to interpret such material because of differences in terminology and lack of precise definition of the terms used. Tischendorf's material revealed erythroblastic hyperplasia with left shift of erythroblasts in all of his 11 patients.<sup>81</sup> Predominance of basophilic forms was mentioned by several authors.<sup>29, 47, 81</sup> According to Limarzi and co-workers the erythroblastic hyperplasia which occurred in their patients was due almost entirely to increase in the number of basophilic normoblasts, the pronormoblasts being significantly increased only rarely. Macronormoblasts were noted by Klima.<sup>47</sup> Isaacs described the marrow in uncomplicated cirrhosis as resembling that of pernicious anemia with megaloblasts present, but we have found no resemblance between the marrows of patients with pernicious anemia in relapse and cirrhosis of the liver. Our definition of the megaloblast has been given in detail elsewhere.<sup>11</sup> Specific denials of the presence of megaloblasts in the bone marrows of patients with cirrhosis of the liver has been made by Klima,<sup>47</sup> Limarzi et al.,<sup>81</sup> Ransier,<sup>72</sup> Benhamou,<sup>4</sup> Loeper and Vignatou,<sup>82</sup> Israels and Wilkinson,<sup>42</sup> and Fiessinger, Dupuy and Laur.<sup>79</sup>

**Granulocytes.** Granulocytic hypoplasia has been reported in patients with cirrhosis.<sup>1, 3, 31, 36</sup> as well as in rats with experimentally induced cirrhosis.<sup>82</sup> When complications such as infection or carcinomatosis are present or following laparotomy the myelogram may show leukopoietic hyperplasia.<sup>65, 84</sup>

\* Our term erythroblast denotes any nucleated red cell regardless of the state of maturation of either nucleus or cytoplasm.

Limarzi et al. observed an average of 26.3 per cent neutrophil myelocytes in the marrows of 20 patients. This represents an increase, as compared with our observations on normal persons.<sup>10</sup> Eosinophil leukocytes are sometimes increased in number even in the absence of eosinophilia in the peripheral blood.<sup>47-51</sup> The majority of reports do not mention alterations in the differential distributions of myeloid leukocytes.

**Lymphocytes.** The earlier studies of postmortem material yielded a few reports of increases of lymphocytes. However, it is unlikely that all the cells designated as small and large lymphocytes could be differentiated from other elements of lymphoid character because sectioned material was used. Rossier<sup>52</sup> described a decrease in the frequency of lymphoid nodules.

**Plasma Cells.** The frequency of plasma cells appears to be quite variable, some authors finding none<sup>53</sup> and others noting increases.<sup>47-51, 79-81</sup> Leitner<sup>80</sup> stated that in cirrhosis of the liver there is an increase of plasma cells, whereas the reverse is true of epidemic hepatitis.

**Reticulum Cells.** The evidence for or against reticulum cell hyperplasia is inconclusive. The usual aspiration technique is not satisfactory for determining the reticulum cell content of marrow, as these cells tend to be arranged in syncytial masses which are difficult to break up to form free cells in the aspirated fluid.<sup>6</sup> Even so, Rohr<sup>82-84</sup> and others<sup>47-50, 79-81</sup> found increased numbers of reticulum cells. Increased phagocytosis of pigment, usually hemosiderin, has been noted in many cases.<sup>81-83, 85-87</sup> Rohr remarked that there was no phagocytosis of fat in the reticulum cells in patients with fatty livers.<sup>83</sup>

**Qualitative Changes in Leukocytes.** Among the reported morphologic changes in the leukocytes are increased anisocytosis of granular elements<sup>79</sup> and vacuolization of monocytes and granulopoietic cells.<sup>81-83, 85</sup> It has been pointed out that the marrow of cirrhosis shows none of the peculiar disturbances of myeloid tissue seen in pernicious anemia,<sup>81</sup> but our material, as will be shown below, reveals that dysplasia of neutrophils, superficially resembling that seen in pernicious anemia, may occur.

**Megakaryocytes.** There are few recorded observations on megakaryocytopoiesis in cirrhosis of the liver, and the various reports are conflicting. This may be expected as the methods for estimating megakaryocyte content of aspirated marrow now in use are generally unsatisfactory.<sup>6-13</sup> Fiessinger, Dupuy, and Laur<sup>29</sup> found no megakaryocytes in the smears of sternal marrow from 10 patients, but Limarzi et al. reported an increased number in all of their 20 patients. Others<sup>1-5</sup> found normal or increased numbers and sometimes an increase of immature forms.

### *Results of the Present Study*

There is no evidence to show variations in the bone marrow picture which could be ascribed to differences in age or sex of adult patients, type, duration or severity of the liver lesion, or the type of anemia present, except that erythropoiesis may be slightly more active in patients with microcytic hypochromic anemia.<sup>4</sup>

**Fat and Cell Content of Marrow and ME Ratios.** Data concerning the relative volumes of fat and nucleated cells, as well as the differential distributions and ME ratios in our series of 25 patients are presented in table 4. The table also includes data from our control cases (19 normal individuals). The fat volumes showed a wide range, from 1 to 8 per cent, and a mean value of 1.8 per cent. The ME volumes ranged from 3 to 26.5 per cent, with a mean value of 13.9 per cent. Others<sup>51</sup> have considered the sternal marrows of patients with hepatic cirrhosis to be about twice as cellular as normal because of the finding of a mean ME volume of 13 per cent. Although this value is in close agreement with our findings in cirrhosis, our normal controls also yielded a mean ME volume of approximately 13 per cent. It has been shown, however, that the volumetric method provides only a crude estimate of relative fat and cell content of aspirated marrow and that it is not reliable for detecting small variations.<sup>8-9</sup> For these reasons, we made estimates of fat and cell content based on sectioned material, using the methods described by Berman and Axelrod.<sup>8-9</sup>

The results of this analysis are shown in table 5. There does not appear to be any large difference between the average relative fat or cell content of sternal marrow from cirrhotic and normal individuals, but the marrows of normal persons

TABLE 4.—*The fat volumes ME volumes ME ratios and differential distributions of nucleated cells in sternal marrow of 19 normal individuals and 25 patients with cirrhosis of the liver*

The data represent percentages. In each case the differential distribution is based on observation of a minimum of 2,000 cells. The symbol N in the first vertical column indicates the average counts on 19 normal persons.

\* Case 22 complicated by chronic lymphatic leukemia

are more likely to have fat contents over 30 per cent than is the case for patients with cirrhosis. The corollary is that the sternal marrows of patients with cirrhosis are likely to be more cellular than normal (table 6).

We found no relationship between the degree of cellularity of the marrow and the severity of the anemia. Hyperplasia of the marrow in cirrhosis occurred in spite

of absence of severe anemia. Hypocellularity is an unusual finding in the marrow of patients with this disease. In all except one case (case 25) the marrow was either normal or increased in cellularity, in spite of absence of signs of accelerated erythropoiesis in the peripheral blood. The conclusion made by Limarzi and co-authors regarding the common occurrence of hypercellularity of the sternal marrow is substantiated by our findings in sectioned material.

Analysis of patients with cirrhosis and of normal individuals as separate groups, as we have done above, may mask variations within the groups. Accordingly, we studied our data in an effort to detect possible relationships between the following groups of factors: fat content of bone marrow and fat content of the liver, ME volume and degree of anemia or severity of the liver lesion, ME ratio and degree

TABLE 5.—*Estimates of relative fat and cell content in sections of aspirated sternal marrow of patients with cirrhosis of the liver, and of normal individuals*

	% fat, range	% fat average	% cells range	% cells average

70% or more cells	0	0	8	47

of anemia, severity of the liver lesion or presence or absence of hemorrhagic phenomena.

The observation by Moosnick, Schleicher and Peterson<sup>40</sup> that choline therapy caused the fatty marrow and liver in a patient with refractory pernicious anemia to revert toward normal suggested a relationship between the fat content of these two organs. In our cirrhosis material there does not appear to be any quantitative relationship.

Low ME ratios were slightly, but not significantly, more frequent among patients with severe liver lesions. In general, patients who had experienced recent hemorrhages had lower ME ratios than the others. In one instance (case 15) a very low and reversed ratio of 0.4:1 occurred in a patient who had been bleeding from esophageal varices. Hence, recent blood loss increases the likelihood of a low ME ratio, which is expressive of relatively increased erythropoiesis, as would be expected, but hemorrhagic phenomena are not the sole contributing factors causing increased erythropoiesis in cirrhosis, as it was present also in patients without history or

evidence of bleeding. We agree with Fellingner and Klima that increased erythropoiesis in cirrhosis may be independent of bleeding.

*Differential Distribution of Erythroblasts* The differential distribution of erythroblasts in the marrow has been considered to be of diagnostic importance in hepatic cirrhosis. A review of the literature does not provide a clear picture of the type of differential pattern which may be expected. Morrison and Samwick<sup>62</sup> proposed an erythroblast-normoblast ratio which indicates the relationship between the number of early erythroblasts to the late erythroblasts (normoblasts). According to them a high erythroblast-normoblast ratio is indicative of disturbed liver function, and is suggestive of liver disease even before the clinical manifestations are apparent. We were not able to confirm this view as regards cirrhosis of the liver. The distributions of erythroblasts in patients with cirrhosis were within the normal range in our material (table 7).

*Qualitative Changes in Erythroblasts* Although no striking changes in the differential distributions of erythroblasts occurred, certain qualitative changes of diagnosis

TABLE 7—Differential distributions of erythroblasts in sternal marrows of 19 normal individuals and 25 patients with cirrhosis of the liver

	Norma		Cirrhosis	
	Range	Av	Range	Av
Pronormoblasts	1-5%	3%	1-4%	2%
Basophilic normoblasts	6-16%	10%	5-17%	9%
Polychromatophilic normoblasts	80-91%	86%	76-92%	87%
Orthochromatophilic normoblasts	0-4%	1%	1-13%	2%

tic significance were found. One patient with microcytic hypochromic anemia (case 2) exhibited a micronormoblastic marrow. The majority of the erythroblasts were small, and in the polychromatophilic stages the nuclei were generally pyknotic. The cytoplasm was poorly hemoglobinized and the cell contours were ragged. This is the type of erythroblasts we expect to find in instances of chronic iron deficiency anemia, as has also been stated by Scott.<sup>81</sup> In the remaining 24 patients, there were 11 (46 per cent) without evidence of qualitative change in the normoblasts, and 13 (54 per cent) with definite abnormalities.

The changes included increase of the diameters of normoblasts in all developmental stages, increase of nuclear diameters, and a disturbance of the nuclear-cytoplasmic ratios. The mean diameter of the large normoblasts was increased but the nuclear pattern, in most cases, was essentially that of normoblasts. The nuclear-cytoplasmic ratio was altered in favor of a relative increase of cytoplasm. The increase of cytoplasm was not as marked as seen in megaloblasts, and the large cells are of the type designated as macronormoblasts.<sup>45</sup> In a few patients, the nuclear structure in the early basophilic stages resembled that of reticulum cells. The reticular characteristics of the nuclei of these macronormoblasts persist throughout all stages of development. Without careful inspection it is easy to confuse such cells with megaloblasts of pernicious anemia, especially in the proerythroblast

stages. The differences between such abnormal large cells and megaloblasts of pernicious anemia have been emphasized by Jones<sup>46</sup> and Downey.<sup>25</sup> The frequency distributions and mean diameters of the polychromatophilic normoblasts in patients with cirrhosis and macronormoblastic marrows differ significantly from normal (fig. 1).

Theoretically, patients with cirrhosis of the liver might be expected to have megaloblastic marrow because of impaired storage of the antipernicious anemia principle, but no examples of such a change in erythropoiesis were seen in our series of 25 patients. Others have also stated that in the presence of cirrhosis of the liver the marrow is macronormoblastic in type.<sup>46</sup> Furthermore, the macrocytic anemias of cirrhosis of the liver do not respond to folic acid therapy in the manner of the macrocytic-megaloblastic anemias of the pernicious type.<sup>11</sup>

FIG. 1.—Typical frequency distribution curves of diameters of polychromatophilic erythroblasts in sternal marrow smears from patients with chronic iron deficiency anemia, cirrhosis of the liver with macrocytic anemia, and a normal individual. The mean diameters are 8.6, 11.1, and 10.0 microns, respectively.

We noted correlation between the presence of macrocytosis in the blood and macronormoblastic erythropoiesis in the marrow. Twelve of 13 patients (92 per cent) with macrocytic anemia had macronormoblastic marrow, whereas 5 of 11 patients (22 per cent) with normoblastic marrow had normocytosis in the peripheral blood, the others having only slight macrocytosis. The change to macrocytosis in the blood originates in dysplasia in the bone marrow, and is not related to factors acting on the red cells after they have entered the circulation.

**Granulocytes and Monocytes.** The differential distributions of the granulopoietic and monocytic cells showed remarkable constancy (table 4). Except in 2 patients (cases 12 and 17), there were no significant deviations from normal. One patient had an elevated percentage of neutrophil promyelocytes (21 per cent). This individual had neutrophilic leukocytosis and evidence of chronic cholecystitis at the time of the marrow aspiration. In the second patient the neutrophil promyelocytes comprised 25 per cent of the myeloid leukocytes. This patient had a marked neutrophilic leukocytosis, fever, and residual drainage following a rib resection eleven days previously, for empyema thoracis. The increases in promyelocytes were

compatible with the reactive change in myeloid leukopoiesis seen in some infections. Infection, as also observed by others,<sup>65-84</sup> may provoke reactive changes in leukopoiesis in patients with cirrhosis, but the differential distributions of myeloid leukocytes appear approximately normal in most cases, regardless of the presence of complications such as jaundice, fever, ascites or bleeding, all of which were present to varying extents among our patients. Others have pointed out the constancy of the marrow pattern in cirrhosis. Fiessinger, Dupuy and Laur<sup>29</sup> remarked that the myelogram was the same regardless of the appearance of icterus, oliguria, purpura, or the agonal state.

*Lymphocytes* In spite of the fairly regular appearance of lymphopenia in the peripheral blood, the marrows contained normal incidences of lymphocytes, except in one patient with 45 per cent lymphocytes (case 22) who had chronic lymphatic leukemia in addition to cirrhosis of the liver.

*Plasma Cells* The frequency of plasma cells is a point of special interest because of conflicting views in various reports. In our control material plasma cells comprise up to 2 per cent of the nucleated cells, exclusive of erythroblasts. A percentage of 4 per cent or more represents a significant increase. Six, or 30 per cent, of our patients had 4 per cent or more plasma cells in the sternal marrow smears. We are loth to accept Leitner's view that the plasma cell content of marrow may be of importance in the differential diagnosis of cirrhosis and epidemic hepatitis.

*Reticulum Cells* We do not regard the percentages of reticulum cells in smears of aspirated marrow as reliable indices of the reticulum cell content of sternal marrow. Such cells are best observed in imprints of marrow particles (Schleicher<sup>78</sup>), as they tend to remain fixed in the marrow tissue. There was no regular increase or decrease in the incidence of reticulum cells in our material, as observed either in the smears made from the first drop of aspirated marrow or from the concentrates of marrow, or from the imprints of marrow particles.

*Qualitative Changes in Leukocytes and Reticulum Cells* We were not able to confirm the previously reported prominence of vacuolization of granulocytes and monocytes in the marrows of patients with hepatic cirrhosis, such changes were of irregular appearance and never very marked. A few marrows revealed morphologic abnormalities of granulopoiesis. These included the appearance of giant band form neutrophils and giant polymorphonuclear neutrophils with hypersegmented nuclei. Such cells have a superficial resemblance to the large cells seen in pernicious anemia. However, there is no marked change in the type of granulation, nor is the chromatin pattern of the nuclei as fine as seen in the typical dysplastic cells associated with megaloblastic marrows. The significance of such changes is obscure. We have observed them occasionally in cases of iron deficiency anemia, in non-megaloblastic nutritional macrocytic anemias not responsive to liver extract therapy, leukemias, and carcinomatosis. The peculiar giant neutrophils were seen in three cases in our series (cases 12, 14, 24), and they were not numerous. We have mentioned them only because of their possible confusion with the characteristic macropolycytes, (Cooke<sup>17</sup>) or pernicious-anemia neutrophils (Jones<sup>42</sup>) of megaloblastic anemias.

In the few cases in which reticulum cells were relatively numerous (over 4 per

cent) the cells were of histiocytic rather than hematopoietic type. The nuclei were those of undifferentiated reticulum cells, and the cytoplasm was faintly acidophilic, abundant, and non-homogeneous, usually with some vacuolization and azurophil granulation, and often containing phagocytosed debris. We found no evidence of fat or lipid storage, but in 4 cases in which the liver contained relatively large amounts of iron-containing pigment, and especially in one case of pigmentary cirrhosis (case 16), the free reticulum cells contained large amounts of iron-containing pigment. The presence of macrophages with phagocytosed hemosiderin would therefore appear to imply that the liver also contains pigment in relatively large amounts.

*Megakaryocytes.* We have experienced difficulty in estimating the megakaryocyte content of aspirated marrow. The inadequacy of methods in use at present have been noted by various authors.<sup>6, 48, 53</sup> In our hands, the estimation of megakaryocytes based on their number in smears, as advocated by Limarzi et al.<sup>51</sup> has not yielded consistent results. Krumbhaar and Custer<sup>48</sup> have shown that reliable estimates can be based on enumeration of these cells in sectioned material. This is in accord with our experience. We have described our procedure for estimating

TABLE 8—*Megakaryocyte counts in normal individuals and in patients with cirrhosis of the liver*

	No. of cases	Range	Mean $\pm$ S. E.
Normals	10	14-60	35.7 $\pm$ 4.8
Cirrhosis	18	13-84	43.4 $\pm$ 5.8

\* Standard error of mean

megakaryocyte content in sectioned particles of aspirated marrow above, under the heading, Cases and Methods. The results in our series of patients are shown in table 8.

In the cirrhosis series, the megakaryocyte counts were slightly higher, on the average, than in the control series, but the difference was not statistically significant. The values obtained in cirrhosis were within normal limits or higher than normal. The point of chief interest is that, in spite of the common occurrence of peripheral thrombocytopenia, the megakaryocyte content of the marrow is normal or elevated in patients with cirrhosis of the liver. In this respect the findings are similar to those observed in instances of thrombocytopenia associated with hyperplasia. There were no important morphologic changes in the megakaryocytes nor changes in their differential distributions.

#### *Discussion of the Bone Marrow Findings*

The evidence from the literature and the information gained from the present study of the marrow in patients with cirrhosis of the liver may be summarized as follows:

1. Extension of red or functioning bone marrow into the shafts of the long bones is of regular occurrence in adults with cirrhosis of the liver.
2. The average relative fat content of the sternal marrow is not significantly

different from that of normal persons, but instances of high relative fat content are less likely to occur in patients with cirrhosis than is the case for normal individuals

3 The cellularity of the bone marrow in both the normal sites of hematopoiesis and in the sites representing extension of active marrow is normal or increased in most instances

4 Although hemorrhage tends to provoke marked relative increase of erythropoiesis, erythroblastic hyperplasia may be independent of bleeding in cirrhosis of the liver

5 The differential distribution of erythroblasts of patients with cirrhosis is not significantly changed, but there is a high degree of correlation between macrocytosis in the peripheral blood and the appearance of macronormoblastic erythropoiesis in the bone marrow. Megaloblastic erythropoiesis is rare, if present at all, in patients with hepatic cirrhosis uncomplicated by pernicious anemia

6 There are no significant changes in differential distributions of cells of the granulocytic, monocytic or lymphocytic series, but infection may result in a relative increase of immature granulocytes, especially promyelocytes. In occasional patients there is a disturbance of granulopoiesis indicated by the appearance of atypical giant neutrophils which are not identical with the characteristic macropolycytes or pernicious-anemia neutrophils associated with megaloblastic marrows

7 There are no constant quantitative changes in plasma cells or reticulum cells, although the finding of numerous reticulum cells containing hemosiderin implies hemosiderosis of the liver in patients with cirrhosis

8 Megakaryocytes are of normal or increased infrequency in the sternal marrows of patients with hepatic cirrhosis, but no qualitative changes of importance occur

It is clear that in patients with hepatic cirrhosis the marrow is of normal or increased cellularity, and that hypocellular marrows are unusual in spite of peripheral anemia which is often characterized by lack of signs of accelerated regeneration of red cells. Even in cases in which the sternal marrow is of normal cellularity, the fat in the shafts of the long bones is replaced by hematopoietically active tissue. With respect to cellularity, the most important change is extension of the marrow organ, since this appears to be more constant than hyperplasia at a given site, such as the sternum. In other words, the total active marrow in the body is increased in amount in cirrhosis of the liver

The fact that normal or relatively increased erythropoiesis is the rule, not only in marrow which is normally cellular, but in marrow which is usually fatty, is of interest because it occurs in spite of careful exclusion of blood loss. It has been suggested that the explanation may be that the patients with cirrhosis suffer a partial deficiency of the antipernicious anemia principle due to deficiency of storage or metabolism in the diseased liver, but the considerations which refute this hypothesis as an explanation for the peripheral macrocytosis apply to the problem of the marrow changes

Since it has been shown that patients with cirrhosis of the liver may excrete abnormally large quantities of urobilinogen,<sup>1 89</sup> we are inclined to believe that

the factor of excessive destruction of erythrocytes may play a role. The erythroblastic hyperplasia and the appearance of macro- and reticulonormoblasts in the marrow can be accounted for on the basis of hemolytic anemia, in which condition such types of erythroblasts are known to appear.<sup>7, 84</sup> The evaluation of the relative importance of hemolysis in the pathogenesis of the anemia is a problem worthy of further study.

The mechanism of hemolysis, if and when it occurs, must be regarded in the light of the concept of hypersplenism.<sup>13, 9, 91</sup> There are a number of peripheral blood and marrow changes which are suggestive of hypersplenism. The peripheral cytopenias (anemia and thrombocytopenia) occur in relation to normal or increased formation of erythroblasts and megakaryocytes in the marrow. These paradoxical phenomena are typical of hypersplenism which, in the case of cirrhosis, should be considered as manifestations of secondary hypersplenism. The well known involvement of the spleen in patients with hepatic cirrhosis is additional evidence in favor of this view.

#### *Diagnostic Significance of Hematologic Studies in Cirrhosis of the Liver*

Our hematologic studies, while controlled by observations on normal persons, have not been extended to other diseases which may be characterized by findings similar to those we have presented. Therefore we cannot consider any of the changes in blood and marrow we have described as pathognomonic of cirrhosis, even though they appear to be characteristic of the disease. This was emphasized by Tischendorf<sup>84</sup> who studied a group of patients with cirrhosis of the liver and other diseases of the liver, gall bladder and biliary tract. He felt that the sternal myelogram was not of value in the differential diagnosis of liver and gall bladder diseases, as some of the findings in these conditions are similar. On the other hand, it is not justifiable to consider complete blood and bone marrow studies as valueless and without diagnostic importance in cirrhosis of the liver.

For example, in patients known to have the disease, the appearance of microcytic hypochromic anemia or micronormoblastic marrow is indicative of chronic blood loss. The presence of hypocellular marrow in patients with macrocytic anemia suspected of having cirrhosis is unusual, and should point to other or additional factors in the clinical picture. Furthermore, although normocytic or macrocytic anemias are compatible with the diagnosis of cirrhosis, macrocytic hypochromic anemia, as determined by the mean corpuscular volume and mean corpuscular hemoglobin values, is not typical and should lead to further study of the patient. The marrow examination may be of crucial importance in distinguishing between pernicious or other megaloblastic anemias and the macrocytic anemia of cirrhosis, as the peripheral blood study does not provide evidence of the type of erythropoiesis in the marrow.<sup>11</sup>

Some patients with cirrhosis of the liver do not present unequivocal clinical signs of their disease. In such cases, we have found that the combined study of the peripheral blood and sternal bone marrow may lead the clinician toward serious consideration of cirrhosis of the liver. The combination of macrocytosis or macrocytic anemia without hypochromasia, plus lymphopenia and thrombocytopenia,

together with the presence of normal or increased marrow cellularity, and normal or increased erythrocytogenesis and megakaryocytopoiesis, constitutes a group of hematological findings which point strongly to cirrhosis of the liver. Furthermore, when anemia is absent and the other findings are present the probability of cirrhosis is even greater. An example of the latter type of case is given in the following brief case report.

*Case 25.* A 53 year old female was admitted for repair of a large abdominal incisional hernia. Systemic review was noncontributory. There was no history of alcoholism. Appetite and food intake were adequate. The preoperative blood protein and prothrombin levels were within normal limits. Because the liver and spleen were palpable the patient was referred for hematological survey. Serum bilirubin and urinary urobilinogen concentrations were normal. The bromsulphthalein test gave normal results. There was no anemia and the erythrocytes were normocytic and normochromic but lymphopenia (930 per cubic millimeter) and thrombocytopenia (57 000 per cubic millimeter) were present. The sternal marrow was hypercellular with a relative increase of erythrocytogenesis and a normal megakaryocyte count. The hematologic findings indicated a diagnosis of cirrhosis of the liver. A biopsy specimen obtained from the liver at the time of repair of the hernia revealed grade 2 cirrhosis.

We have found the combined blood and sternal marrow study useful in establishing the diagnosis of cirrhosis of the liver in patients in whom other diseases have obscured its manifestations, or in whom historical evidence was absent so that the clinical diagnosis was difficult to make.

#### SUMMARY

The peripheral blood and bone marrow findings in patients with cirrhosis of the liver have been analyzed on the basis of a review of the literature and the authors' study of 25 patients with diagnoses verified by biopsy of the liver.

The principal blood findings are macrocytic or normocytic anemia with normal or elevated mean corpuscular hemoglobin values, lymphopenia and thrombocytopenia in the majority of cases.

Anemia may be independent of bleeding, and the severity of anemia or macrocytosis does not appear to be related to the severity of the liver lesion.

The consistent change in the bone marrow is extension of the marrow organ so that active hematopoiesis is found in the shafts of the long bones.

Regardless of the presence or absence of bleeding or anemia, the marrow of the sternum is of normal or increased cellularity, with normal or increased erythrocytogenesis and megakaryocytopoiesis in most cases.

Hypocellularity of the marrow is an unusual finding, even in patients with advanced liver lesions.

Macronormoblastic erythropoiesis is seen in patients with macrocytic anemia, but megaloblastic erythropoiesis does not result from cirrhosis of the liver.

The presence of peripheral cytopenias (anemia and thrombocytopenia) in spite of normal or increased formation of erythroblasts and megakaryocytes in the marrow is suggestive of hypersplenism in patients with hepatic cirrhosis.

In patients with chronic hemorrhage the blood and bone marrow pictures are those of iron deficiency anemia, although other changes such as lymphopenia and thrombocytopenia tend to persist.

The combined peripheral blood and sternal marrow examination is often of value in establishing the diagnosis of cirrhosis of the liver

## APPENDIX

### Case Reports

*Case 1* White male age 61 with history of diabetes ascites two years Examination hepatosplenomegaly ascites edema of ankles no hemorrhagic phenomena RBC 2,790,000 Hb 7.8 grams MCV 91 MCH 28 WBC 5 500 platelets 144 000 Clinical impression hepatic cirrhosis, diabetes mellitus. Liver biopsy cirrhosis grade 3

*Case 2* White male age 55 with history of alcoholism ascites three weeks Examination hepatomegaly ascites spider angiomas loss of axillary and pubic hair no hemorrhagic phenomena RBC 3 710,000, Hb 9.3 grams, MCV 97 MCH 25 WBC 5 300 platelets 90,000 Clinical impression hepatic cirrhosis. Liver biopsy cirrhosis grade 4

*Case 3* White male age 45 with history of alcoholism ascites three weeks Examination hepatomegaly, ascites edema of ankles icterus spider angiomas, no hemorrhagic phenomena RBC 3 560,000 Hb 11.0 grams, MCV 96 MCH 31 WBC 11 000, platelets 150,000 Clinical impression hepatic cirrhosis. Liver biopsy cirrhosis grade 4

*Case 4* White female age 48 with history of alcoholism ascites and edema of ankles two weeks Examination hepatosplenomegaly ascites edema of lower extremities icterus spider angiomas no hemorrhagic phenomena RBC 3 760,000 Hb 10.9 grams MCV 90 MCH 29, WBC 12,500 platelets 200 000. Clinical impression hepatic cirrhosis Liver biopsy cirrhosis grade 4

*Case 5* Negro female age 31 hospitalized for meningitis from which uneventful recovery was made No history of alcoholism Examination hepatosplenomegaly RBC 2,970,000 Hb 10.1 grams MCV 121, MCH 34, WBC 6 650, platelets 220 000 Clinical impression probable hepatic cirrhosis but blood dyscrasia to be ruled out Liver biopsy cirrhosis grade 2.

*Case 6* White male age 52 with history of alcoholism icterus ascites edema of ankles two weeks Examination hepatomegaly ascites edema of ankles icterus no hemorrhagic phenomena RBC 3,070 000, Hb 10.7 grams, MCV 130 MCH 35 WBC 6 500 platelets 77,000 Clinical impression acute hepatitis superimposed on hepatic cirrhosis Liver biopsy cirrhosis grade 3

*Case 7* White male age 59 with history of alcoholism ascites and edema of lower extremities three weeks Examination hepatomegaly ascites edema of legs spider angiomas melena RBC 3 840,000 Hb 11.3 grams MCV 101 MCH 29 WBC 8 500 platelets 108 000 Clinical impression hepatic cirrhosis Liver biopsy cirrhosis, grade 3

*Case 8* White female age 31 with history of alcoholism hematemesis Examination hepatomegaly no hemorrhagic phenomena RBC 3 790 000 Hb 12.8 grams MCV 103 MCH 34 WBC 7 650 platelets 100 000 Clinical impression hepatic cirrhosis Liver biopsy cirrhosis grade 1

*Case 9* White male age 52 with history of alcoholism ascites one year Examination hepatosplenomegaly ascites no hemorrhagic phenomena RBC 3 700 000 Hb 11.5 grams MCV 97 MCH 30 WBC 3,350 platelets 111 000 Clinical impression hepatic cirrhosis Liver biopsy cirrhosis grade 1

*Case 10* White male age 38 with history of alcoholism icterus and weight loss five months Examination hepatosplenomegaly ascites icterus melena RBC 3 580 000 Hb 9.9 grams MCV 94 MCH 25 WBC 4 950 platelets 150 000 Clinical impression hepatic cirrhosis bleeding hemorrhoids Liver biopsy cirrhosis grade 1

*Case 11* White male age 59 with history of alcoholism icterus and weight loss four weeks Examination hepatosplenomegaly icterus melena RBC 4 200,000 Hb 12.6 grams MCV 98 MCH 28 WBC 10 450 platelets 230,000 Clinical impression acute hepatitis superimposed on hepatic cirrhosis terminal uremia Liver biopsy cirrhosis grade 2.

*Case 12* White female age 32 with history of alcoholism icterus followed by ascites four weeks Examination hepatomegaly ascites icterus spider angiomas fever no hemorrhagic phenomena RBC 2,590,000 Hb 8.7 grams MCV 135 MCH 25 WBC 11 350 platelets 126 000 Clinical impression hepatic cirrhosis chronic cholecystitis Liver biopsy cirrhosis grade 4

*Case 13* Negro male age 49 with history of alcoholism syphilis, icterus three weeks Examination

hepatomegaly slight icterus, no hemorrhagic phenomena RBC 4,950,000 Hb 15.4 grams, MCV 105 MCH 31, WBC 7,550, platelets 280,000 Clinical impression hepatic cirrhosis, hepatoma, or hepar lobatum Liver biopsy cirrhosis, grade 4, hepatoma

*Case 14* White male age 38 with history of alcoholism, weakness, nausea, vomiting icterus, ascites two months Examination hepatosplenomegaly ascites, edema of feet icterus spider angiomas, melena RBC 2,450,000 Hb 8.0 grams MCD 7.5 microns MCH 33 WBC 23,300 platelets 42,000 Clinical impression hepatic cirrhosis Liver biopsy cirrhosis grade 1 Autopsy cirrhosis, grade 1, acute suppurative pancreatitis

*Case 15* White male age 43 intermittent epistaxis, icterus weight loss five years Examination hepatosplenomegaly, ascites, icterus, melena RBC 3,870,000, Hb 8.4 grams MCV 72, MCH 22, WBC 4,850, platelets 94,000 Clinical impression biliary cirrhosis Liver biopsy cirrhosis grade 3

*Case 16* White male age 57 with diagnosis of cirrhosis of the liver and diabetes mellitus four years before present admission Examination hepatomegaly pigmentation of skin, no hemorrhagic phenomena RBC 3,810,000, Hb 12.8 grams MCV 100, MCH 34, WBC 10,500, platelets 160,000 Clinical impression hemochromatosis Skin biopsy hemochromatosis Liver biopsy pigmentary cirrhosis grade 4

*Case 17* White male age 62 with history of alcoholism diabetes mellitus seven years cough, weight loss one year Examination hepatomegaly spider angiomas, fever empyema thoracis, no hemorrhagic phenomena RBC 4,350,000, Hb 13.3 grams, MCV 95 MCH 31 WBC 24,500, platelets 143,000 Clinical impression hepatic cirrhosis empyema thoracis diabetes mellitus Liver biopsy cirrhosis grade 2.

*Case 18* White male age 46 mentally incompetent since infancy, anorexia, vomiting icterus one week Examination hepatomegaly, abdominal distension, icterus no hemorrhagic phenomena RBC 4,000,000 Hb 12.0 grams, MCV 100 MCH 30, WBC 10,800, platelets 321,600 Clinical impression infectious hepatitis Liver biopsy cirrhosis grade 1

*Case 19* White male age 59 with history of alcoholism, hematemesis, melena two weeks Examination hepatomegaly, ascites edema of ankles, loss of pubic hair melena RBC 3,610,000 Hb 9.9 grams, MCV 94 MCH 27, WBC 8,000, platelets 100,000 Clinical impression hepatic cirrhosis Liver biopsy cirrhosis, grade 4

*Case 20* White male age 68 with history of alcoholism, progressive weight loss ascites of unknown duration Examination ascites, no hepatosplenomegaly, no hemorrhagic phenomena RBC 4,730,000 Hb 12.0 grams MCV 97 MCH 25, WBC 12,050, platelets 288,000 Clinical impression hepatic cirrhosis Liver biopsy cirrhosis, grade 3

*Case 21* Negro male age 43 with history of alcoholism weight loss peri umbilical pain, nausea, three weeks Examination hepatosplenomegaly slight ascites icterus no hemorrhagic phenomena RBC 3,660,000, Hb 10.4 grams MCD 7.6 microns MCH 29 WBC 13,950, platelets 400,000 Clinical impression hepatic cirrhosis Liver biopsy cirrhosis, grade 2.

*Case 22* White female age 65 known to have had hypertension many years, progressive dyspnea and dependent edema of unknown duration Examination hepatosplenomegaly hypertensive retinopathy left ventricular enlargement, left pleural effusion no lymph node enlargement, no hemorrhagic phenomena RBC 5,000,000 Hb 14.7 grams MCV 94 MCH 29, WBC 47,200 platelets 201,000 Clinical impression hypertensive cardiovascular disease with decompensation chronic lymphatic leukemia Liver biopsy cirrhosis, grade 2. chronic lymphatic leukemia

*Case 23* White male age 71 with history of hematemesis ascites three years Examination hepatosplenomegaly esophageal varices, ascites RBC 2,750,000, Hb 7.0 grams, MCV 89 MCH 25 WBC 3,800 platelets 132,000 Clinical impression hepatic cirrhosis Liver biopsy cirrhosis grade 2.

*Case 24* White male age 58 with history of alcoholism progressive ascites edema weakness six years Examination hepatomegaly ascites spider angiomas no hemorrhagic phenomena coarse tremor left hand RBC 4,620,000 Hb 11.6 grams, MCV 91, MCH 25 WBC 5,900, platelets 193,000 Clinical impression hepatic cirrhosis Parkinsonism Liver biopsy cirrhosis grade 2.

*Case 25* White female age 53 with history of diverticulitis followed by peritoneal abscesses, colostomy, and colostomy repair two years before present admission Readmitted for repair of large incisional abdominal hernia Examination hepatosplenomegaly large abdominal hernia no hemorrhagic phenomena RBC 4,330,000 Hb 12.3 grams MCV 88 MCH 28 WBC 3,200 platelets 57,000 Clinical impression incisional hernia mild diabetes mellitus possible hepatic cirrhosis or blood dyscrasia. Liver biopsy cirrhosis grade 2.

# AN EVALUATION OF STERNAL ASPIRATION AS AN AID IN DIAGNOSIS OF THE MALIGNANT LYMPHOMATA

By TALBERT COOPER, M D , AND CHARLES H WATKINS, M D

THE DIAGNOSIS of malignant lymphoma can be definitely established only by histologic examination of the tissue involved. In the majority of instances palpably enlarged superficial lymph nodes are present and properly performed biopsy provides the correct diagnosis in a direct and relatively simple manner. However, in a significant number of cases of Hodgkin's disease, lymphosarcoma and follicular lymphoma the primary site of involvement is thoracic, abdominal or some otherwise inaccessible location for simple biopsy.

Symmers<sup>1</sup> has stated that in Hodgkin's disease primary enlargement of abdominal or of abdominal and thoracic nodes combined is ten times more common than primary enlargement of the cervical nodes. Ewing<sup>2</sup> supported this view, emphasizing that the superficial nodes which first attract attention may be only the outlying manifestations of an internal lesion. Jackson and Parker<sup>3</sup> found the superficial nodes primarily involved in all of 26 cases of Hodgkin's paraganuloma, but in only 8 of 59 cases of Hodgkin's granuloma, and in none of 27 cases of Hodgkin's sarcoma. Sugarbaker and Craver<sup>4</sup> regarded the primary site of involvement as extranodal in approximately one third of 196 cases of lymphosarcoma. In 14.2 per cent of cases in which lymph nodes were involved primarily, the site of origin was abdominal or mediastinal. These observations contrast clearly with the common impression that superficial lymph nodes, particularly those of the cervical area, constitute the usual site of primary involvement in these conditions.

Biopsy of superficial nodes, then, may be of no value in establishing a diagnosis in some cases and of value only after the disease process is well advanced in others.

This study was undertaken in an attempt to evaluate the clinical usefulness of aspiration of sternal bone marrow as a method for obtaining material of diagnostic significance in cases of malignant lymphoma.

## REVIEW OF THE LITERATURE

### *Bone or bone marrow involvement in cases of malignant lymphoma*

*Hodgkin's disease.* The dominant histologic change in Hodgkin's disease involves the reticular cells of the reticulo-endothelial system. The lymphatic elements do not take an active part in the hyperplasia in most cases and often are diminished in number.<sup>5</sup> It might reasonably be expected that an organ rich in reticulo-endothelial tissue as is the bone marrow would be commonly involved in the disease. Steiner,<sup>6</sup> in his comprehensive review of the subject, suggested that bony lesions might develop in one of three ways (1) by direct invasion from contiguous

Abridgment of thesis submitted by Dr. Cooper to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Medicine.

lymphogranulomatous masses, (2) by hematogenous spread or (3) by primary origin in the marrow

Krumbhaar<sup>7</sup> reported a case of Hodgkin's disease of the bone marrow and spleen without apparent involvement of lymph nodes. Herscher<sup>8</sup> and Livingston<sup>9</sup> observed cases in which, at autopsy, the process appeared to be confined to the bones and liver.

The reported incidence of bone or bone marrow involvement in Hodgkin's disease is highly variable, particularly in studies based on clinical evidence alone. In summarizing the reported series in which the diagnosis of bone or bone marrow involvement was based on clinical grounds, Steiner<sup>6</sup> determined an average incidence of 8.3 per cent (166 of 2,006 cases). Lesions of bone most frequently involving the spinal column and pelvis, were noted during life in 23 per cent of Jackson and Parker's<sup>3</sup> 133 cases of Hodgkin's granuloma. Similar lesions were detected in 14.8 per cent of 257 cases of Hodgkin's disease reported by Vieta and co-workers.<sup>10</sup> The latter authors called attention to cases of extensive marrow involvement discovered at postmortem examination in which the same bones had appeared normal on previous roentgenologic examination. The degree of cortical involvement appears to determine to a considerable extent the roentgenographic appearance of bone, and extensive medullary lesions may not be detected by this method.

According to Ewing,<sup>11</sup> bone marrow lesions, both typical and atypical, form a prominent feature in many cases of Hodgkin's disease, at times they may dominate the clinical course and it is rare that a thorough search at autopsy fails to disclose some deposits in the bone marrow. Steiner<sup>6</sup> noted an average incidence of 28.3 per cent of bony lesions in 547 reported autopsies but observed that the incidence reported from any series apparently depended on the thoroughness of the skeletal examination. He studied microscopic sections taken at random from 3 to 9 easily accessible bones in 14 cases of Hodgkin's disease and found marrow lesions in 78.6 per cent of cases. The vertebrae, pelvis, ribs, femur, sternum, skull and humerus were most commonly involved. Sixty-three and seven-tenths per cent of sternal sections contained lymphogranulomatous lesions. Steiner<sup>6</sup> further observed that there was no basis for the impression that skeletal lesions occur only as a late manifestation of Hodgkin's disease.

*Lymphosarcoma.* By original definition,<sup>12</sup> lymphosarcoma lacks the systemic character of Hodgkin's disease and leukemia. Arising as an apparently local change in lymphadenoid tissue, it seems to extend by local invasion, by continuous growth through lymph channels and by the formation of true metastatic lesions in distant organs.

Lymph vessels have not been demonstrated in bone marrow but small accumulations of lymphatic tissue along the small arteries have been described by most investigators.<sup>13</sup> Lymphosarcoma might, then, arise in the bone marrow but this structure would seem no more likely to become secondarily involved than would any other organ.

Sugarbaker and Craver<sup>4</sup> noted clinical evidence of bony involvement in 9.7 per cent of 196 cases of lymphosarcoma. In 1 per cent, the process appeared to arise in bone marrow. Vieta and co-workers<sup>10</sup> found roentgenologic evidence of bony

involvement in 7 per cent of 213 cases, while on postmortem examination lesions were noted in 29 per cent of 54 cases. The authors regarded the latter figure as probably too low since the examinations at necropsy were limited to easily accessible bones and the skeletal examination was sometimes omitted entirely. Lesions of bone in this series were most often a late manifestation of the disease. Such lesions appeared in only 22 per cent of cases during the first half of the course of the illness while in 63 per cent the bony involvement appeared to develop during the terminal one third of the illness. By contrast, in cases of Hodgkin's disease observed by the same authors, 37 per cent of the bony lesions were clinically evident before the first half of the course of the disease had elapsed. It was further observed that while the bony lesions in lymphosarcoma were, as in Hodgkin's disease, most common in the bones rich in red marrow there was a tendency for a more generalized distribution of lymphosarcomatous lesions to occur.

The less detailed observations of other authors<sup>11-14-18</sup> would indicate that bone marrow involvement in lymphosarcoma occurs infrequently and then as a manifestation of a late, generalized stage of the disease.

*Follicular lymphoma* Sugarbaker and Craver<sup>4</sup> have regarded follicular lymphoma as a setting for lymphosarcoma since later biopsies in several of their cases have shown the development of typical reticulum cell lymphosarcoma. Whatever the exact relationship between the two processes may be, it appears to be an intimate one.

Gall and co-workers<sup>19</sup> noted bony lesions (clinically evident) in 6 of a series of 63 cases of the follicular type of malignant lymphoma.

#### *Reported clinical experience with sternal aspiration in cases of malignant lymphoma*

*Hodgkin's disease* Young and Osgood<sup>20</sup> found that study of specimens of aspirated sternal marrow was of no diagnostic value in 2 cases of Hodgkin's disease. Vogel and co-workers<sup>21</sup> observed a slight left shift and, in a few cases, an increase in eosinophils and reticulum cells. It was noted that 3 of the 5 patients studied had received intensive irradiation therapy during the year preceding the examination of the sternal marrow. Émile-Weil and Perlès<sup>22</sup> obtained negative or inconclusive results in most cases. In 10 of 25 instances, medullary hyperplasia was noted. A slight increase in polymorphonuclear neutrophils, eosinophils, plasma cells and monocytes was commonly observed. Although no Reed-Sternberg cells were noted the authors suggested that the differentiation of such cells from megakaryocytes would be difficult. Paraf and co-workers<sup>23</sup> reported 1 case in which a sternal tumor was present. Sternal aspirations at three sites yielded material suggesting only erythromyeloid aplasia with lymphocytes and plasma cells predominant. After study of the findings in 14 cases Falconer and Leonard<sup>24</sup> observed the sternal marrow in this group in some instances showed a leukemoid or myeloid reaction difficult to distinguish from the early myeloid reaction of myelogenous leukemia. In only 1 case was the specimen of sternal marrow the basis for the diagnosis of Hodgkin's disease, a trephine specimen which revealed fibrosis was obtained in this case.

Scott<sup>25</sup> examined specimens in 8 cases and concluded that the findings, while

dependent on the stage of the disease, were variable and nonspecific. In none were Reed-Sternberg cells found. In 3 there were varying degrees of myeloid left shift. In 2 some increase in number of megakaryocytes was noted. One patient presented aplastic changes which were attributed to previous irradiation therapy. Baras-cutti<sup>26</sup> reported 6 cases in which marked eosinophilia of the marrow occurred. Mendell and co-workers<sup>27</sup> noted no characteristic changes in specimens of marrow from 3 patients. Propp and Schwind<sup>28</sup> stated that myelophthisic anemia such as occurs in Hodgkin's disease and reticulosis are among the diseases giving marrow pictures which are not diagnostic. Piney and Hamilton-Paterson<sup>29</sup> stated that we probably never obtain assistance in diagnosis by examining the bone marrow in Hodgkin's disease and described hyperplastic and hypoplastic changes in varying stages of the disease. Sundberg<sup>30</sup> and Wintrobe<sup>31</sup> agreed that the usually encountered marrow picture is nonspecific, consisting of some shift to the left in the myeloid line together with a slight monocytosis or eosinophilia. Limarzi<sup>32</sup> reported myeloid hyperplasia, an increase in plasma cells, histiocytes and megakaryocytes in some cases of Hodgkin's disease.

While the majority of investigators have found aspiration of sternal marrow of little value as a diagnostic procedure in Hodgkin's disease, there are a few exceptions. Váradi<sup>33</sup> reported a single case in which sternal aspiration yielded a specimen containing many lymphocytes and large basophilic cells with large nuclei and large, blue nucleoli which he classified as Reed-Sternberg cells. Rohr and Hegglin<sup>34</sup> identified Reed-Sternberg cells in the specimen of marrow in a case of Hodgkin's disease. Klima<sup>35</sup> described a lymphogranulomazellen, which he felt to be a derivative of the lymphoblast, as the characteristic cell of Hodgkin's disease. Scott<sup>36</sup> regarded the cell described by Klima as a partly differentiated reticulum cell such as is frequently seen in imprint and puncture preparations from lymph nodes of many conditions other than Hodgkin's disease. From 1 patient Sundberg<sup>30</sup> described section preparations showing the granulomatous lesions typical of Hodgkin's disease, but only after an extremely diligent search was a single Reed-Sternberg cell found in smear preparations from the same patient.

*Lymphosarcoma.* Dameshek and co-workers<sup>36</sup> in illustrating the comparative value and limitations of trephine and simple aspiration methods of sternal marrow biopsy reported 2 cases of lymphosarcoma. On attempted aspiration no cells were obtained in 1 and very few cells in the other case. Study of sections obtained by the trephine method established the diagnosis in each case, disclosing lymphosarcomatosis with connective tissue replacement of the marrow in the first, and a small area of lymphoblastic proliferation (lymphosarcoma) in the second. Vogel and co-workers<sup>37</sup> reported the marrow findings essentially normal in 4 cases of lymphosarcoma and in 2 of follicular lymphoma. Falconer and Leonard<sup>38</sup> found that study of aspirated marrow material was of no aid to diagnosis in 4 cases of lymphosarcoma. Wintrobe<sup>31</sup> noted an increase of lymphocytes in some cases of lymphocytic lymphoma and in 1 of follicular lymphoma, but more commonly he found no abnormality in the marrow in such cases. Gormsen,<sup>39</sup> in 2 of 18 cases of lymphosarcoma, observed moderate infiltration of the sternal marrow with more or less immature lymphatic elements.

## MATERIAL AND METHODS

*Material* The material for this study was obtained by simple needle aspiration of sternal bone marrow in 15 unselected cases of Hodgkin's disease, 10 of lymphosarcoma and 2 of follicular lymphoma. The diagnosis in each case was based on results of lymph node biopsy, autopsy or both.

Because of the uniformly poor results reported following examination of simple smears after needle aspiration, no cases were included in this series in which examination was carried out prior to the introduction, for routine use in this laboratory, of the methods of preparation advocated by Schleicher.<sup>28, 29</sup>

*Technic* With the Illinois sternal aspiration needle\* a total of approximately 2 cc of sternal marrow substance was aspirated. The specimen was transferred immediately to a paraffin-lined container and mixed gently with a minute pinch of heparin powder as an anticoagulant.

Portions of the material obtained were used for preparation of the usual smears, Wright's stain (Grübler) being used and for volumetric determinations. The latter procedure has been found to provide a fairly accurate quantitative index of the functional state of the marrow.

The grossly visible particles of marrow substance, or units, in the aspirated specimens were carefully collected. These units ranged from 0.5 to 1.0 mm in diameter in the normal individual to as much as 0.3 to 4.0 mm in the hyperplastic marrow of pernicious anemia. Several of these units were speared on the tip of a wooden applicator and the material smeared out gently on the surface of a glass slide. The resulting imprint preparations provided a picture of the general structural relationships of the marrow.

Finally, after fixation, the remaining units were stained with hematoxylin and eosin and section preparations obtained. Sections so prepared provide architecturally and histologically accurate samples of the marrow. With this method, it has been felt that the needle aspiration method more closely approaches a true biopsy procedure, and the advantages of the trephine method have been, to a considerable extent, overcome. It was hoped that aspirated material so prepared would yield information of diagnostic significance in circumstances in which the simpler aspiration and smear techniques had reportedly failed.

*Plan of study* The preparations described above were carefully examined. Differential counts of 1,000 nucleated cells were carried out in each case. The clinical features in the cases under consideration were analyzed and some correlation with the appearance of the marrow specimen was attempted.

## RESULTS OF STUDY

*Hodgkin's disease*

*Criteria for diagnosis* Hodgkin's disease of the bone marrow exhibits the same histologic picture seen in other involved tissues and organs. Hyperplasia of reticular cells is often the dominant change.<sup>3</sup> However, the process is characterized by

\* Manufactured by the V. Mueller Co., Chicago, Ill.

pleomorphism and the diagnosis rests finally on the demonstration of the presence of Reed-Sternberg cells, whether the pathologic change be paraganulomatous, granulomatous or sarcomatous in type.<sup>2</sup>

Piney and Hamilton-Paterson<sup>29</sup> have stated that there is no certain way of distinguishing Reed-Sternberg cells from megakaryocytes. While it is true that the differentiation may be difficult, it is felt that it can be satisfactorily accomplished in most instances if undistorted, properly stained cells are considered.

The mature cells are similar in size. The nuclei of Reed-Sternberg cells are round, oval, lobulated, multilobed or multinucleated. The nuclear chromatin is relatively

FIG. 1—REED-STERNBERG CELLS. Imprints of lymph nodes from a patient with Hodgkin's disease. *a* Wright's stain  $\times 970$ . *b* Hematoxylin and eosin stain  $\times 970$ .

scanty in amount and irregularly distributed (fig. 1). Megakaryocytic nuclei, although often multilobed, are always single with generous, more uniformly distributed chromatin and a fine chromatin-parachromatin pattern. The outstanding characteristic of the Reed-Sternberg cell is the very prominent nucleolus (fig. 1*b*) which is usually lacking in the megakaryocyte or megakaryoblast. The cytoplasm of the normal megakaryocyte contains characteristic azurophilic granulation when stained with the polychrome dyes. In addition, pseudopodia with apparent platelet formation are often observed. The generous cytoplasm of the Reed-Sternberg cell has a faintly basophilic, granular appearance with Wright's stain and the cell membrane is often indistinct.

**Results.** Detailed search of all material obtained by sternal aspiration in the

proved cases of Hodgkin's disease in this series revealed no Reed-Sternberg cells. Satisfactory section preparations were obtained in 9 instances but in none were lesions suggestive of Hodgkin's disease demonstrable.

In 6 instances, the specimen of marrow appeared normally active, and in 5 there was distinct hyperplasia. Other variations from normal in this group were minor in degree and of nonspecific character, consisting of myeloid preponderance with slight shift to the left in 5, mild eosinophilia in 3, toxic changes in cells of the myeloid series in 4 and diminished erythrogenic activity in 3. One or more of these changes was present in each case.

In the remaining 4 cases, attempted aspiration resulted in a relatively dry tap, although a few drops of marrow were obtained from which smears were made. Such a result with this procedure in the hands of an experienced individual should, per se, raise suspicion of disease of the marrow. It has occurred most often in cases of myelofibrosis, acute leukemia and metastatic carcinoma involving the bone marrow. In Hodgkin's disease the attempted aspiration is probably defeated by the fibrous character or hypercellular consistency of the involved tissue. In this connection, Loseke and Craver<sup>10</sup> experienced difficulty in obtaining satisfactory or sufficiently large specimens in 11 of 25 cases of Hodgkin's disease in which needle aspiration of lymph nodes and other involved tissues was attempted. Smear preparations in 1 of the 4 dry tap cases revealed few normal marrow elements with small lymphocytes composing 91 per cent of the nucleated cells, in the remaining 3 cases there was an increase in number of morphologically normal lymphocytes with moderate reduction in number of erythrogenic and myeloid cells. It should be emphasized that despite the negative findings on sternal aspiration, demonstrable bone or bone marrow involvement was present in 4 cases of this series. The dorsolumbar vertebrae were the site of the clinically evident lesions in 3 while in the remaining case the clavicles and several ribs were involved.

No correlation could be established between the marrow findings and the duration of the disease, the apparent degree of dissemination of the process, the amount of previous irradiation therapy or the peripheral blood picture. A mild to moderately severe anemia, hypochromic in type, was noted in 11 of the 15 cases in this group. The anemia was accompanied by evidence of active regeneration of erythrocytes, including the presence of macrocytes and polychromatophilia, in 9 instances. Monocytosis was noted in 6, myeloid immaturity in 4 and eosinophilia in 3.

*Comment.* No consistent abnormalities or diagnostically specific changes were encountered in the study of sternal marrow material in this series of cases of Hodgkin's disease.

The occurrence of dry taps in 4 instances was regarded as suggestive of marrow involvement but careful examination of the smears made from the meager specimens obtained disclosed nothing of diagnostic significance.

The lesions of the bone marrow in Hodgkin's disease may be focal and of microscopic proportions or extensive and grossly demonstrable.<sup>6</sup> When small, focal lesions exist, chance alone might account for disappointing results on attempted needle aspiration. Aspiration of marrow material from several sternal sites, from vertebral bodies, and perhaps, from the iliac crest might enhance the diagnostic po-

tentialities of the procedure. In addition, the sternum should be routinely palpated for areas of tenderness and such localities should be selected as the site for aspiration.

The fibrosis which so commonly develops in the lesions of Hodgkin's disease could conceivably render simple aspiration of a satisfactory specimen impossible. Utilization of the trephine method, in dry tap cases particularly, might overcome this difficulty.

The high incidence of positive findings on sections taken at random post mortem by Steiner<sup>6</sup> would indicate that more frequent positive results should follow the adoption of the proper technic. This should be particularly true in patients presenting clinical<sup>41</sup> or hematologic evidence of bone marrow involvement.

### *Lymphosarcoma*

*Criteria for diagnosis.* No one cell has been shown to be diagnostic of lymphosarcoma. Ghon and Roman<sup>42</sup> emphasized the usual presence of a mixture of cells and commented that lymphosarcoma appears to be a neoplasm in which all elements of the normal lymph node may be represented. These cells ranged from typical small lymphocytes through larger, atypical cells with indented, hyperchromatic nuclei and relatively little cytoplasm, to lymphoblastic cells with reticular nuclear structure, sometimes containing nucleoli, and a basophilic, often vacuolated, cytoplasm. Lymphocytic, lymphoblastic and reticulum cell varieties of lymphosarcoma have been commonly described.<sup>14</sup> Gall and Mallory<sup>43</sup> subdivided lymphosarcoma into stem cell, clasmatocytic, lymphoblastic and lymphocytic types, according to the predominant cell type. Hellwig<sup>44</sup> has advanced a similar classification.

Sternberg,<sup>45</sup> however, described a cell which he regarded as characteristic of lymphosarcoma, occurring in cases of so-called leukosarcoma. Sternberg considered the cell a form of lymphocyte but, at the same time, an atypical tumor cell. The majority of hematologists have not accepted leukosarcoma as an entity and prefer to consider it a locally aggressive type of leukemia, most often large cell and acute in type.<sup>16</sup>

Isaacs<sup>46</sup> noted the development of leukocytosis in 15 of 43 cases of lymphosarcoma. He described a characteristic cell appearing in the peripheral blood in those cases of lymphosarcoma cell leukemia which he felt was usually mistaken for an immature lymphocyte or lymphoblast. Certain distinguishing features of the nucleoli were stressed. When stained with Wright's stain after the material has been smeared on cover slips treated with cresyl blue, the nucleolus stands out as a sky blue, round area surrounded by a deep blue-black rim of cytoplasm which is piled up around it. Such nucleoli were usually single. In contrast, nucleoli of immature lymphocytes or lymphoblasts appeared as a light blue hole in the chromatin structure, without the heavily staining rim. In addition, the chromatin around the edge of the nucleus of the lymphosarcoma cell was thickened into a fairly definite nuclear wall. In 6 of the 15 cases in this group necropsy disclosed transformation, in varying degrees, of all lymphoid tissue in the body into the lymphosarcoma type. The autopsy findings cited in these cases would seem more consistent with the diagnosis of leukemia than lymphosarcoma.

Wiseman<sup>47</sup> said it is possible, by use of vital staining methods, to differentiate normal, leukemic and lymphosarcomatous lymphocytes

Gall and Mallory<sup>48</sup> considered the development of a leukemic blood picture an incidental manifestation of the underlying neoplastic process in lymphosarcoma. Blood pictures resembling leukemia occurred at some time in the course of the disease in 18 per cent of the lymphocytomas and in 28 per cent of the lymphoblastomas reviewed by Hellwig.<sup>49</sup> Evans and Leucutia<sup>48</sup> advanced the concept that lymphosarcoma becomes leukemia when the bone marrow is involved.

Webster<sup>49</sup> regarded lymphosarcoma, lymphatic leukemia and leukosarcoma as manifestations of the same disease. There appears to be little doubt that the processes are closely related, and absolute differentiation is commonly difficult and sometimes impossible.

In addition to the doubtful existence, according to the majority of investigators, of a cell characteristic of the disease, the positive microscopic diagnosis of lymphosarcoma is further complicated in that the general histologic picture may be closely simulated in other conditions, notably Hodgkin's sarcoma and lymphatic leukemia. Potter<sup>50</sup> suggested that the diagnosis of small cell lymphosarcoma should be eliminated from consideration in lymph node enlargements and labeled leukemia.

*Results of study.* Material permitting satisfactory section, imprint and smear preparations was obtained in all cases in this group, however, the technical difficulty encountered was sufficient to warrant the designation dry tap in 2 instances.

In 3 cases the specimen of marrow presented no remarkable deviation from the normal. Lymphocytosis, ranging from 30.6 to 70.9 per cent with an average of 46.2 per cent, was present in the remaining 7 cases. The lymphocytosis was accompanied by moderate to marked diminution in number of erythrogenic cells. In contrast to the frequent finding of myeloid hyperplasia with left shift in cases of Hodgkin's disease, such changes were not observed in this group.

The fixed sections presented the most spectacular findings. In 3 instances the marrow was infiltrated or invaded by obviously abnormal tissue composed of mononuclear cells (fig. 2). The picture presented was one of focal involvement, with apparently uninvolved marrow tissue interspersed. This contrasts with the usual appearance of the marrow in lymphatic leukemia (fig. 3) in which, while nodules of lymphocytes may be present, the involvement is usually more diffuse in character. This difference may not be striking on superficial examination (figs. 3a and 4a) but on closer study cells of the myeloid and megakaryocytic series can be identified even in a densely infiltrated marrow in chronic lymphatic leukemia (fig. 3b). On the other hand, no normal marrow elements can be identified among the lymphocytic cells composing the infiltrate in cases of lymphosarcoma (fig. 4). Whether this distinction will be sufficiently consistent to be regarded as definitely diagnostic can be determined only by study of more cases.

Fixed sections in the remaining cases appeared normal in 3 instances and presented varying degrees of hypoplasia, without aggregations of mononuclear cells, in 4.

In 3 cases there was no significant deviation from the normal either in the morphologic character of the lymphocytes or in other features observed on the smear preparations. Atypical and abnormal lymphocytic types were present in all 7 cases in which there was some degree of lymphocytosis in the marrow specimen. No single lymphocytic type predominated in these cases but rather a variety of forms was encountered on the smear preparations. The prevailing types could be loosely separated into the following categories:

FIG. 2.—LYMPHOSARCOMATOUS INFILTRATION OF BONE MARROW. Section preparation (Hematoxylin and eosin stain  $\times 90$ ).

**Type 1.** This was a large (10 to 18 micra) round to oval cell containing an irregularly shaped, frequently indented nucleus with relatively scanty, basophilic cytoplasm (fig. 5a). The dense chromatin material was uniformly distributed with little parachromatin evident. Distinct nucleoli were fairly numerous.

**Type 2.** Similar in size (14 to 18 micra) to the cells described as type 1, this cell (fig. 5b) demonstrated less bizarre nuclear configuration and more generous, basophilic cytoplasm. The nuclear structure was reticular with frequent grooving and occasional indistinct nucleoli. A clear perinuclear zone was occasionally observed.

**Type 3.** These cells (fig. 5b) were 8 to 12 micra in diameter and presented dense, hyperchromatic, frequently grooved, occasionally Rieder-type nuclei with a very

thin rim of deeply basophilic cytoplasm. This was the abnormal cell type most commonly encountered.

**Type 4** These cells (fig 5c), measuring 14 to 20 micra in diameter, appeared much like normal large lymphocytes but contained smoothed out, irregular shaped, often eccentrically placed nuclei with rare indistinct nucleoli. The cytoplasm was sky blue in color and presented occasional azure granules.

These atypical or abnormal cells were seen in company with varying proportions of lymphocytes having a morphologically normal appearance. While a single type of abnormal cell was usually predominant in each case a mixture of types was most

FIG 3 —SECTION PREPARATIONS OF MARROW FROM A PATIENT WITH LYMPHATIC LEUKEMIA STAINED WITH HEMATOXYLIN AND EOSIN *a*  $\times 105$  *b*  $\times 700$

commonly encountered (fig 5b). No correlation could be made in this series between the type of cell predominating in the sternal smear and the type according to the morphologic classification advanced after biopsy and autopsy.

The cell types observed might be confused with, or may indeed be identical with, atypical or bizarre forms sometimes encountered in subacute or acute lymphatic leukemia but are clearly distinguishable from the ordinary lymphocyte or lymphoblast.

In 5 of the 7 cases in which atypical lymphocytes were demonstrated in the marrow specimen, similar cells were observed in smears of the peripheral blood. In 4 of these, including the 3 cases in which there were positive fixed sections, peripheral lymphocytosis ranging from 36 to 64 per cent was noted at some time

# STERNAL ASPIRATION IN MALIGNANT LYMPHOMATA

during the period of observation. The total leukocyte count per cubic millimeter of blood ranged from 3,700 to 17,500 for the entire group.

No other abnormalities were consistently noted on study of the peripheral blood in these cases although minor degrees of myeloid immaturity and erythrocytic regeneration were occasionally observed. Despite the diminution in number of erythrogenic cells commonly noted (7 cases) on examination of sternal specimens, mild normocytic anemia occurred in only 2 cases.

No clinical evidence of bony involvement was noted in this group. In all cases superficial lymph nodes were palpably enlarged, the lymphadenopathy involving the anterior cervical, axillary and inguinal groups with approximately the same frequency. The spleen was palpably enlarged in 60 per cent. In no case was remarkable hepatomegaly demonstrated. The duration of symptoms prior to sternal aspiration ranged from two months to five years with the average duration of illness being shorter (eleven months) in the patients presenting most marked changes in the bone marrow. A history of previous irradiation therapy was elicited in 4 cases but could not be correlated with the findings noted on examination of the marrow in these cases.

*Comment.* The high incidence of abnormal findings in this group of cases was surprising. It is felt that the demonstration of lymphocytic tumor infiltrates in the bone marrow should have the same diagnostic significance as the same finding in a lymph node or other tissue would have. The greatest difficulty will probably be experienced in histologically differentiating this picture from that of lymphatic leukemia.

While the specific diagnostic significance of the abnormal cell types encountered in 7 of the 10 cases in this group must be further evaluated, their presence in the bone marrow or peripheral blood would appear to justify the suspicion that lymphosarcoma exists.

## Follicular lymphoma

This condition, which appears to be closely related to lymphosarcoma, is characterized histopathologically by the development in lymphoid tissue of multiple, follicle-like nodules of variable size.<sup>21</sup> The predominant cell type in such a process has been described as an ordinary lymphocyte or lymphoblast.<sup>14, 43, 51</sup>

In 2 cases reported by Baggenstoss and Heck,<sup>51</sup> later biopsies revealed the picture of lymphosarcoma.

Satisfactory specimens were obtained in the 2 cases composing this group. In 1 instance there was a slight increase in number (20 per cent of nucleated cells) of morphologically normal lymphocytes. In the other, a hyperplastic specimen with preponderance of the myeloid line was obtained. Neither presented features of diagnostic significance.

In each, the spleen and superficial lymph nodes were moderately enlarged. The marrow lymphocytosis noted in the first case was not reflected in the peripheral blood which, but for a mild normocytic anemia, appeared normal. In the second case, leukopenia (1,400 leukocytes per cubic millimeter of whole blood) with a relative lymphocytosis and monocytosis was present. The patient had recently

completed a course of irradiation therapy before examination at the clinic. Symptoms had developed twelve to eighteen months prior to sternal aspiration. No clinical evidence of bony involvement was demonstrated in either case.

*Comment* While sternal aspiration in these cases provided no information of diagnostic significance it is felt that, in view of the close relationship between follicular lymphoma and lymphosarcoma, study of a larger series of cases may well reveal more significant changes.

### SUMMARY AND CONCLUSIONS

Neither diagnostically significant features nor consistent abnormalities of other character were demonstrated in the specimens of sternal marrow obtained in 15 cases of Hodgkin's disease. With improvements in technic, particularly in patients presenting clinical evidence of bone or bone marrow involvement, the procedure might become more valuable.

As an aid in diagnosis in cases of obscure malignant lymphoma, sternal aspiration is likely to prove of greatest value in cases of lymphosarcoma. In 7 of 10 proved cases, abnormal lymphocytic cell types were encountered and in 3 instances bone marrow infiltrations were demonstrated in fixed section preparations. The latter were felt to be diagnostic of lymphosarcoma.

In 2 cases of follicular lymphoma the specimens of sternal marrow presented no striking abnormalities. However, because of the apparently close relationship which this disease bears to lymphosarcoma it is felt that study of a larger number of cases may prove the procedure of some diagnostic value.

## BONE MARROW REGENERATION IN EXPERIMENTAL BENZENE INTOXICATION

By BERNHARD STEINBERG, M D

**B**ENZENE intoxication is known to affect the hemopoietic system of man and of lower animals. Depending upon the duration of exposure, concentration of the chemical, frequency of administration and the age of the animal, changes of the bone marrow vary from complete aplasia to selective hypoplasia. Since little is known of the regulating mechanism of production and distribution of leukocytes, the action of hemopoietic intoxicants may be utilized for the study of this problem. This work was undertaken from that point of view.

The mechanism by which benzene induces bone marrow changes has not been determined. Two possibilities appear plausible in the present state of our knowledge. The chemical may inhibit cell division or interfere with hypothetic active principles concerned with marrow activity. Cell division may be inhibited either by damage to the nucleus or by the alteration of the lipid-protein medium of the marrow in which the cells are contained. The latter process presupposes that the *cell metabolism requires the integrity of the medium*.

### EXPERIMENTAL PROCEDURE

This study is a morphologic investigation of the effect of benzene on cell division. The following experimental procedures were employed for the evaluation: (1) Marrow of one or more of the long bones was extirpated in living rabbits according to a procedure described previously.<sup>1</sup> (2) Various degrees of benzene intoxication were induced in rabbits. (3) The animals were killed at intervals after varying periods of benzene administration. (4) Studies were made of the comparative changes between the extirpated and the controlateral unextirpated marrows. (5) Comparative changes were studied between extirpated marrow of normal animals and those with benzene intoxication. The steps in regeneration of extirpated marrow in normal animals were presented in a previous publication.<sup>2</sup>

Extirpation of marrow was done by incising the soft tissues at each end of the long bone. In the removal of tibial marrow the two incisions are preferable. At the narrow end of the bone, the tendons were retracted. At the broad end a cross incision was made to the periosteum. In the case of the femur, humerus, radius and ulna, a single incision from the proximal to the distal end is sufficient. The muscles were separated along fascial lines and were retracted. Muscle injury is the common cause of death of the animals. A single opening was made at the narrow end and four openings at the broad end with a Rask drill. The piece of bone outlined by the four openings was lifted out. A tight-fitting flexible silver cannula was inserted into the single opening. A syringe filled with sterile liquid petrolatum was attached to the cannula. The pressure of the oil separated the marrow and expressed it out of the bone cavity through the larger opening. Occasionally it was necessary to cut each end of the marrow before it could be expressed. The marrow from the epiphyses was removed with a sharp curet and packed first with soft bone wax followed by strips of gauze saturated with wax. The marrow cavity was then cleaned with a pipe cleaner and flushed out with saline (fig. 1). The animal of choice is the rabbit. It is the largest of the animals with a tubular marrow and lends itself for hematologic studies. The animals were anesthetized with pentobarbital sodium. The hair was removed with a depilatory preparation and the leg was wrapped with cotton saturated with an antiseptic. It is essential that the surgical procedure be carried out under strict aseptic precautions.

Forty marrows were extirpated in 30 rabbits in this study. The age of the animals ranged from 3 to 12

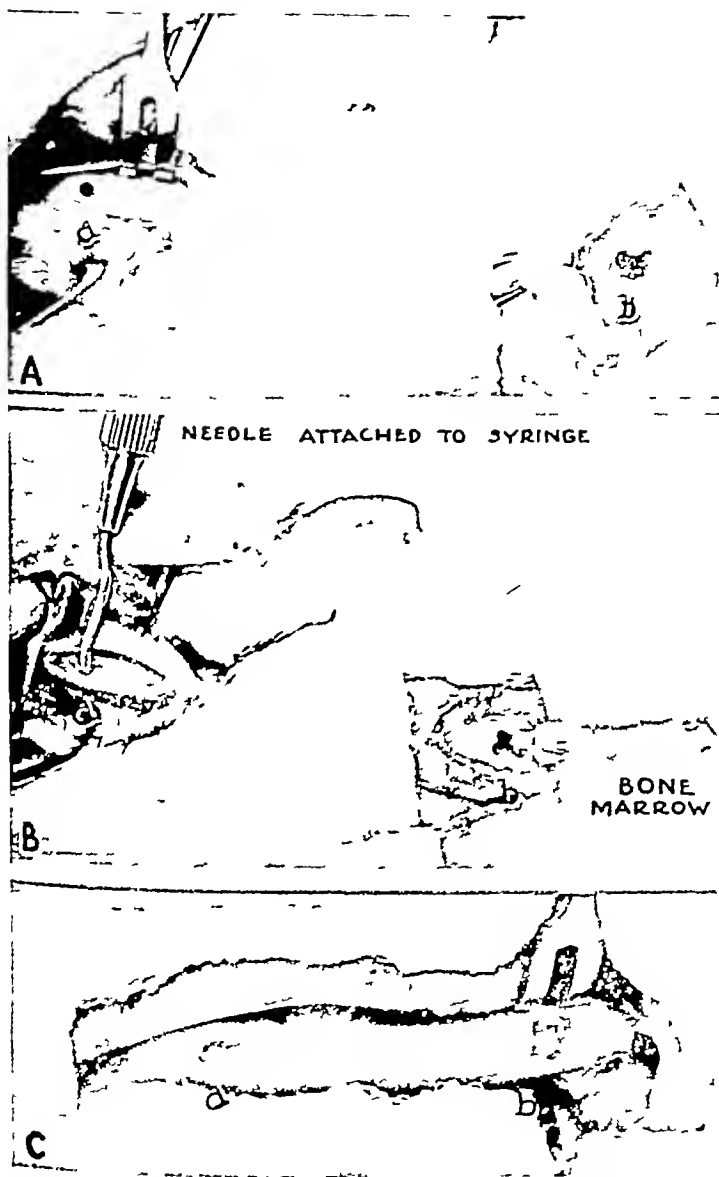

FIG. 1—REMOVAL OF MARROW FROM A LONG BONE OF A LIVING RABBIT

Holes are drilled in the bone with a Rask nail drill. At one end of the bone a single hole is made (a in A). At the opposite end four holes are made and the central bone spicule is removed leaving a large opening (b in A). A flexible silver cannula is inserted into the single hole (a in B) and with a syringe containing oil or water the marrow is expressed through the larger opening (b in B). Both openings are then sealed with bone wax (a and b in C).

months. The animals were given 1 cc. of a mixture of 5 parts of benzene to 1 part of olive oil subcutaneously one to two times daily. The number of injections was varied for each animal (see table 1). Peripheral leukocyte counts were done one or more times daily. The animals were killed at intervals of 3 to 81 days after extirpation of marrow. Studies were made of the comparative changes of the regenerated marrow after fixation in formaldehyde or Bouin's solutions and staining with hematoxylin-eosin or Giemsa preparations.

## RESULTS

### *Regeneration of Normal Marrow*

For a clearer understanding of the comparative changes, the steps in the regeneration of normal marrow are restated. The earliest significant manifestation, which appears in about nine days, is a sprouting of sheets of primitive reticular cells and bone trabeculae from the endosteum. The next step is the formation of fat cells. This process takes place probably by a coalescence of two or more primitive reticular cells after their cytoplasm is replaced by lipids. Fat cells continue to form for sixty days, but their formation is most active and profuse in the first twenty days after extirpation. Islands of myeloid tissue begin to appear in about nine days and increase progressively in number. Regeneration does not proceed uniformly throughout the bone marrow. In sixty days, most of the marrow has returned to a normal number and distribution of myeloid tissue (fig. 2).

### *Regeneration of Marrow in Benzene Intoxication*

The quantity of benzene and the number of injections were varied. Some animals received relatively little of the chemical over a period of a few or many days. Other rabbits were injected almost daily and received a total large quantity of benzene (see table 1). There was a distinct correlation between the degree of intoxication and the appearance of the bone marrow. In severe poisoning, regeneration did not proceed further than the stage of sprouting of primitive reticular cells. There was some attempt to form fat cells, but they were few and atrophic or rudimentary. Whenever an occasional fat cell did develop, it was followed first by proliferation of a few megakaryocytes and then by an infrequent small focus of erythroblasts.

Even after a period of eighty-one days, those animals which received benzene continuously showed a state of marrow response comparable only to the first phase of normal marrow regeneration. Granulocytes did not make their appearance unless a considerable number of fat cells developed and not until both megakaryocytes and cells of the erythrocytic series were present in moderate numbers. A decreasing degree of intoxication was associated with formation of fat cells and myeloid activity. With a relatively small quantity of benzene, fat cells and myeloid tissue was in considerable evidence in twenty-one days after extirpation of the marrow. When benzene administration was stopped, the marrow in the extirpated bone proceeded to develop fat cells, whereas in the intact contralateral marrow, myeloid hemopoiesis would set in.

The significant changes in these experiments consist in the inability of the marrow to regenerate past the primitive reticular cells and the apparent dependence of myeloid activity upon presence of fat cells.

FIG. 2.—A B AND C REGENERATION OF EXTIRPATED MARROW IN NORMAL RABBITS

- A 9 days after extirpation Bone trabeculae and sheets of primitive reticular cells apparently derived from the endosteal layer of bone and from the trabeculae  $\times 100$
- B 20 days after extirpation Formation of fat cells Intermediate forms of primitive reticular cells and erythroblasts are in the field  $\times 720$
- C 30 days after extirpation Islands of myeloid tissue composed of granulocytes and erythroblasts An occasional area of primitive reticular cells  $\times 720$
- D Normal active marrow of a rabbit for comparison  $\times 540$

FIG. 3—A AND B REGENERATION OF EXTIRPATED MARROW IN SEVERE BENZENE INTOXICATION

A 54 days after extirpation There are indistinct sheets of primitive reticular cells rudimentary fat cells and megakaryoblasts  $\times 720$

B 81 days after extirpation There are sheets of primitive reticular cells bone trabeculae and rudimentary fat cells but no myeloid activity  $\times 720$

C Intact marrow of same animal as in A There are atrophied fat cells and erythroblastic activity  $\times 540$

D Intact marrow of same animal as in B The fat cells are atrophic There is no myeloid activity  $\times 540$

*Effects of Benzene Intoxication on Intact Bone Marrow*

The intact bone marrow in benzene intoxication will be described only in so far as it helps to clarify the picture of regeneration. Whenever possible, comparisons were made with marrow from controlateral extirpated bones. Marrow from

TABLE 1 — *Relationship of Degree of Benzene Intoxication to Bone Marrow Regeneration*

Period of marrow regeneration	Extent of benzene administration	Range of WBC per cu. mm. of blood during benzene administration	State of the regenerated bone marrow in benzene intoxication
days			
14	9 cc. of benzene for 6 days	1800 to 422	No myeloid cells few fat cells, sheets of primitive reticular cells and bone trabeculae
19	21 cc. of benzene for 11 days	2600 to 420	No myeloid cells no fat cells sheets of primitive reticular cells and bone trabeculae
21	10 cc. of benzene for 7 days	5900 to 2120	Considerable myeloid activity many fat cells and an occasional sheet of primitive reticular cells
30	34 cc. of benzene for 19 days	8900 to 1300	Few areas of myeloid regeneration largely erythroblastic few fat cells extensive sheets of primitive reticular cells and bone trabeculae
32	12 cc. of benzene for 7 days	8160 to 2100	Considerable myeloid activity many fat cells, few areas of primitive reticular cells
30	46 cc. of benzene for 30 days	5700 to 1000	No myeloid regeneration infrequent rudimentary fat cell, extensive sheets of primitive reticular cells and bone trabeculae
33	30 cc. of benzene for 15 days No benzene for 10 days prior to extirpation 5 days during experiment and 5 days before death	6600 to 1086	No myeloid cells few rudimentary fat cells extensive sheets of primitive reticular cells and bone trabeculae
54	93 cc. of benzene for 51 days	7900 to 1850	An occasional megakaryoblast and erythroblast small number of poorly formed fat cells sheets of primitive reticular cells and bone trabeculae
81	157 cc. of benzene for 70 days	9950 to 3100	Few areas of megakaryocytes, few rudimentary fat cells sheets of primitive reticular cells and bone trabeculae

the humerus, femur, radius, ulna and occasionally the ribs was studied. Sheets of primitive reticular cells were not found in any of the marrow even after eighty-one days of benzene administration. The fat cells remained intact in most instances up to fifty-four days. They became atrophic and the nuclei migrated from the periphery to the center of the fat cell in eighty-one days. In some instances of severe in-

## METHOD

We have used the following method to obtain marrow from various small animals (rabbit, guinea pig, mouse and chicken). From small animals such as 8 day old rabbits, guinea pigs and mice, only a few drops of marrow are obtained. From the chicken and from older rabbits (2½ to 8 pounds), 0.5 to 1 c.c. of fluid may be aspirated. At present we are attempting to establish normal myelograms for rabbits of various ages, as a result the majority of our aspirations have been done on rabbits.

The rabbit, under ether anesthesia, is placed on its back, and its legs are secured in the outstretched position. The site of puncture (fig. 1) is the superior medial surface of the tibia inferior to the medial condyle and medial to the tibial tuberosity. This surface is triangular in shape and can be palpated with ease even in extremely small animals. The superficial hair is removed. In the remainder of the procedure, reasonable and adequate precautions with regard to sterile technic are taken. (The needle is allowed to remain in zephiran chloride for several minutes and the operator keeps his fingers moist with the same solution.) We have used the Klima Rosseger needle\* as a biopsy needle but a shortened lumbar puncture needle with a tightly fitting stylet would probably be adequate. A 15 gage needle is preferable for the

FIG. 1.—ANTERIOR VIEW OF UPPER PORTION OF RIGHT TIBIA OF RABBIT. a Arrow points to site of puncture. b Medial condyle. c Tuberosity.

larger animals. The skin and subcutaneous tissue at the site of puncture are extremely thin. When minimal pressure is applied, the tip of the needle penetrates the superficial tissues and pierces the periosteum. When the periosteum has been penetrated the needle is pushed perpendicularly through the cortex of the tibia until the sudden give sensation indicative of penetration into the medullary cavity is felt. This sudden decrease in resistance to pressure is experienced when attempting to penetrate the cortical bone of any of the adult animals. In young animals, the give sensation is minimal and one may have to judge the depth of penetration by the presence of fat droplets on the stylet. When the marrow cavity has been penetrated the stylet is removed and a 20 cc. syringe is attached. Rapid, strong suction (negative pressure of 10 to 20 cc.) is employed. This usually is followed by the swelling up of marrow into the syringe. Occasionally it is necessary to apply suction more than once in order to obtain fluid, for the marrow may be extremely viscous. Varying amounts of fluid can be obtained, 0.5 cc. is a convenient amount. The needle is removed from the bone and pressure is applied to the wound. Bleeding subsides readily, and no other treatment is required.

The remainder of the method corresponds to that used in the preparation of human sternal marrow for study.<sup>12</sup> The fluid is immediately transferred to a paraffin lined vial containing a minute amount of heparin.† After it has been thoroughly agitated the heparinized marrow is poured out on a clean glass plate. Grossly visible particles of marrow are usually present. The fluid and about half of the particles are transferred to a Wintrobe hematocrit tube by means of a chemically clean capillary pipet. The remaining particles are prepared for microscopic examination by the following method.

\* Made by V. Mueller and Company, Chicago, Illinois.

† Lot 152, Hyoscoo, Westcott and Dunning, Baltimore, Md.

Fix particles in Zenker's fluid—30 minutes to 1 hour

In the remainder of the procedure, remove the fluids from the small vial by means of a capillary pipet. Do not attempt to remove the particles. The timing varies with the size of the particles. A suggested timing is several changes of distilled water—30 minutes 30% alcohol—30 minutes 50% alcohol—1 hour or longer 70% alcohol—1 hour or longer 95% alcohol—10 minutes 100% alcohol (1)—5 minutes 100% alcohol (2)—5 minutes (Add about an equal volume of xylol to this last alcohol almost immediately.) xylol (1)—10 minutes xylol (2)—10 minutes

Remove xylol pour paraffin (M.P. 54°) in vial and allow tissue to become infiltrated in oven for 30 to 45 minutes. Remove paraffin with heated capillary pipet add fresh paraffin and leave in oven for 30 to 45 minutes. Do not leave tissues in oven over 1½ hours.

Remove particles from paraffin by means of a heated capillary pipet. Place tip of pipet at bottom of paraffin-filled boat and force particles out of pipet. The particles should be made to aggregate in a relatively compact mass near the bottom of the boat. Let paraffin harden, pare blocks cut at 5 micra and mount. Stain as desired. Any of the special blood stains can be used following Zenker's fixation. During the staining procedure remove the precipitated mercury. Immediately before staining immerse slides in dilute alcoholic iodine. When the tissue is yellow place slides in a 5 per cent aqueous solution of sodium thiosulphate. Leave slides in thiosulphate until yellow color has faded. Wash in distilled water and continue staining procedure.

The fluid portion is centrifuged at 2500 r.p.m. for eight minutes and readings corresponding to the height of the various strata are taken from the Wintrobe tube. Four main layers (fat plasma myeloid-erythroid, and erythrocytes) are present. Sometimes immediately below the fat layer a layer which consists of a mixture of fat perivascular cells and nucleated marrow cells is found. (These layers give a rough idea of the cellularity of the marrow but sections provide more accurate information in this respect. One of the main advantages of centrifugation is the concentration of nucleated marrow cells to the myeloid-erythroid layer.) The fat and mixed layer are removed and discarded. With a second pipet the myeloid-erythroid layer and a small amount of plasma are transferred to a paraffin lined watch glass. Smears are made from this mixture. The smears are dried rapidly by whipping them through the air or by means of a fan. The smears may be stained with any of the common blood stains. Wright's or the May-Grunwald Giemsa stains are excellent.

Smears made in this way surpass any we have obtained in previous studies of the bone marrow of animals. The smears show isolated undamaged cells in great numbers and are as good for morphologic studies as are those made from human sternal or iliac marrow. Also, as many as thirty cellular smears have been made from a single sample, this has proved valuable for teaching purposes. It has been possible to obtain particulate marrow for sections from almost every rabbit and chicken biopsy.

The procedure described is, of course, not necessary to the study of qualitative changes in the marrow cells. If one withdraws only a few drops of marrow, there is little dilution with sinusoidal blood, and relatively cellular direct smears can be made.

The ease with which marrow can be obtained seems to depend upon the size of the animal and upon the contour of the tibia. Obtaining marrow from the tibia of the guinea pig is reasonably difficult. An 18 gage needle was used, and it was necessary to penetrate at an angle which allowed the needle to be directed toward the shaft of the bone to avoid penetration of the lateral surface of the tibia. In the mouse, the problem is even greater. A short 22 gage needle with an extremely short bevel can be pushed through the cortex of the tibia without too much difficulty. We found it simpler to clear the needle with its stylet after penetrating the cavity rather than attempting to penetrate the bone with the stylet in place.

The needle should be directed toward the shaft of the bone. Only a few drops of marrow were obtained from the guinea pig and the mouse.

No marrow could be aspirated from the tibia or femur of rats. The tibia of the rat has no easily palpable triangular surface. The anterior tibial crest is prominent, and the lateral and medial surfaces of the tibia are in close apposition. When the pressure required for penetration of the cortex of the medial surface was applied, the lateral surface was also penetrated.

The method was not used on dogs, cats, or fowl other than the chicken. Both dogs and cats have triangular surfaces on the medial aspects of their tibias. Except in large dogs, the bone could probably be penetrated with manual pressure.

When 0.5 to 1.0 cc. of fluid are aspirated from the tibia of an adult rabbit, approximately two-thirds of the red marrow in the upper extremity of the bone is evacuated. In one rabbit, aspiration was repeated on days 7, 14, and 30. Only a small amount of fluid was obtained on days 7 and 14, and the percentage of marrow elements was small. One month after the initial biopsy, the fluid was reasonably abundant, but the percentage of immature cells was lower than that in the original marrow. Although repeated biopsies are possible, our method involves aspiration of a large amount of marrow. Biopsies of the same tibia would probably not yield comparable specimens until two months had elapsed.<sup>11</sup>

Aspirations of iliac marrow have been done on rabbits and mice. Approximately 0.5 cc. of fluid can be aspirated from the ilium of the rabbit and treated in the same manner as that obtained from the tibia. Only a few drops of marrow can be aspirated from the ilium of the mouse.

### SUMMARY

1. Methods of aspirating tibial bone marrow from living laboratory animals (rabbit, guinea pig, mouse, and chicken) have been described. No method of aspirating marrow from living mice has been encountered in the literature.

2. The method would probably prove useful in obtaining marrow from the tibia of any small laboratory animal which has a flattened triangular area on the superior medial surface of the tibia.

3. In larger animals (rabbit and chicken), large amounts of marrow can be aspirated. Both smears and sections can be made.

4. The present method, if used in combination with the similar method of aspirating marrow from the ilium, will afford four different sites of aspiration. This should make possible the study of progressive changes in the marrow.

# THE OCCURRENCE OF THE PERIODIC ACID-SCHIFF REACTION IN VARIOUS NORMAL CELLS OF BLOOD AND CONNECTIVE TISSUE

By GEORGE B. WISLOCKI, M.D., JACK J. RHEINGOLD, M.D.,  
AND EDWARD W. DEMPSEY, Ph.D.

THE PERIODIC acid-Schiff method stains glycogen, mucus, reticulum and basement membranes, some kinds of elastic tissue, fibrin, and various substances of quite unknown composition (McManus<sup>1</sup>, Lillie et al.<sup>2</sup>, Wislocki and Dempsey<sup>3</sup>). Glycogen may be differentiated from these other substances by the fact that it is soluble in saliva.

In applying recent histochemical methods to hematology, we have observed the staining reactions of a variety of normal blood and connective tissue cells by the periodic acid-Schiff procedure. The present paper gives a detailed account of these observations with interpretations of the findings.

## MATERIAL AND METHODS

The principal tissues used were obtained from man and rhesus monkey. The human material consisted of smears of peripheral blood and bone marrow of normal subjects, as well as pieces of uterine tube, uterine cervix, vermiform appendix and mammary gland obtained from operative specimens. A few smears of patients with chronic lymphatic leukemia were also examined. Peripheral blood was obtained by finger puncture and marrow by aspiration usually from the sternum.

The material from young rhesus monkeys (*Macaca mulatta*) comprised bone marrow, spleen, lymph glands and pieces of connective tissue from the mediastinum, peritoneum and skin.

In addition to these, occasional tissues from rabbit (bone marrow of a young animal), sow (endometrial stroma) and rat (various areas of connective tissue) were utilized.

The blood and bone marrow smears as well as the blocks of tissue were fixed in Rossman's mixture (sat. sol. picric acid in abs. alc., 90 cm.<sup>3</sup> formaldehyde (added just before using) 10 cm.<sup>3</sup>). The blocks were embedded in paraffin and sections were cut at 5  $\mu$ . Both the smears and the deparaffinized sections were stained by the periodic acid-Schiff technique. After this fixation and method of staining, glycogen, some acid mucopolysaccharides, fibrin and other substances are stained red or pink. Glycogen is distinguishable from mucus and other positively reacting substances by the use of control sections exposed to saliva. Control sections were placed in saliva at room temperature for one hour before staining them. The periodic acid-Schiff method was applied according to the directions of McManus<sup>1</sup> in slightly modified form. The smears and deparaffinized sections were treated with a 1 per cent solution of periodic acid for five minutes, followed by Schiff's leukofuchsin reagent for fifteen minutes and subsequent rinsing in sulfurous acid. When a counterstain seemed desirable, light green or hematoxylin was used. The sections were then dehydrated in alcohols, cleared in xylol and mounted in balsam.

Besides the regular use of saliva on control sections for the identification of glycogen, a few sections of rabbit and monkey bone marrows were exposed to malt diastase (Fisher Scientific Co.—Eimer and

From the Department of Anatomy, Harvard Medical School, Boston, Mass.

This work was done in part under a grant from the American Cancer Society on the recommendation of the Committee on Growth of the National Research Council to Dr. George B. Wislocki, Department of Anatomy, Harvard Medical School, and in part under a grant from the U. S. Public Health Service to Dr. William Dameshek, Department of Medicine, Tufts College Medical School, for the study of Mediterranean anemia.

\* The human blood and bone marrow was obtained from the Hematological Laboratory of The Pratt Diagnostic Hospital, Boston, Massachusetts, through the interest and courtesy of Dr. William Dameshek.

Amend) The sections were incubated for one hour at 37 C in a 1 per cent solution of malt diastase buffered with phosphate at pH 6.8. The results obtained with diastase differed in some respects from those following the use of saliva as will be discussed in a subsequent passage.

The connective tissues enumerated above were drawn into the investigation for the purpose of studying mast cells and tissue eosinophils. To identify these two cell types with certainty, sections were prepared from the same regions after the use of other fixatives and stains. For the cross checking of mast cells, blocks of tissue were fixed for twelve hours in a 4 per cent solution of basic lead acetate and the sections were stained for thirty minutes in a  $\frac{1}{2}$  per cent aqueous solution of toluidin blue according to the method of Holmgren and Wilander<sup>4</sup> and Holmgren.<sup>5</sup> By this procedure the granules of the mast cells become brilliantly metachromatic. For the identification of eosinophils in connective tissue or bone marrow, blocks fixed in Zenker's fluid were sectioned and stained in eosin and methylene blue. Following this procedure the eosinophils are readily distinguishable by their red-stained granules. Blood platelets, megakaryocytes and polymorphonuclear neutrophils could be readily identified in the periodic acid-Schiff preparations without resorting to other means for checking them. Basophilic leukocytes were uncommon but readily recognizable in peripheral blood. Lymphocytes and monocytes were investigated in human blood smears and in sections of spleen and lymph glands of the monkey.

#### OBSERVATIONS ON MAST CELLS AND TISSUE EOSINOPHILS

*Mast cells* In the connective tissues of man and rhesus monkey mast cells stained quite intensely following the periodic acid-Schiff procedure (fig. 1a). Stained mast cells were encountered in the stroma of the human mammary gland, uterine tube and cervix and, in the monkey, in the stroma of the skin, mediastinum and retroperitoneal tissue. The granules were quite heavily stained but the cytoplasm was also involved to some degree, giving a certain haziness to the granules. The reaction was not abolished by previous treatment with saliva, a result which indicated that the staining was not due to glycogen.

Mast cells encountered in the mucosa of sows' uteri also stained deeply by the periodic acid-Schiff procedure, but the granules were less distinctly differentiated than in the mast cells of monkey and man. This staining was not prevented by previous treatment with saliva. On the other hand, the mast cells in the connective tissues of the rat were rarely and, at best, faintly stained.

In contrast to these species differences, the mast cells of all of these animals exhibited uniform and intense metachromasia of their granules following staining with toluidin blue. Instead of being hazy, the metachromatic reaction was sharply confined to the granules.

*Tissue eosinophils* These cells were found by chance in great abundance in the mucosa of a human vermiform appendix. The eosinophils were easily identified by virtue of their brilliant red granules in sections stained with eosin and methylene blue. By the periodic acid-Schiff technic these same cells exhibited a diffuse reddish staining involving both granules and cytoplasm. This staining was not influenced by treatment with saliva and consequently could not be attributed to glycogen.

#### OBSERVATIONS ON CELLS OF BONE MARROW AND PERIPHERAL BLOOD

*Basophilic leukocytes* Basophilic leukocytes were occasionally picked up in human blood smears. Following the periodic acid procedure, they exhibited a number of brilliantly stained, sharply outlined, small red dots located in a pale pink cytoplasm (fig. 1c). In several control smears exposed to saliva, we were unable to identify any basophils, so that the red-stained material may have been glycogen. This appar-

ent finding needs further verification. In the event that basophilic leukocytes contain glycogen, they would appear to differ from mast cells which contain periodic acid-Schiff positive material which is insoluble in saliva.

*Eosinophilic leukocytes* Eosinophilic leukocytes encountered in human blood smears showed a pink to reddish cytoplasm with clear granules. This staining diminished some, but did not disappear entirely after preliminary exposure of the sections to saliva.

Eosinophilic leukocytes in monkey's bone marrow were quite deeply stained, the granules appearing dark red against a paler background. This staining was not prevented by treatment with saliva (fig 1c). These cells stood out most conspicuously in preparations of marrow which had been treated with saliva which removed the similarly stained glycogen from the neutrophilic leukocytes.

The eosinophilic leukocytes of rabbit's bone marrow contained exceptionally large granules which stained a pale red by the periodic acid technique (fig 1d). The staining of these granules was not influenced by previous treatment with saliva.

*Neutrophilic leukocytes and myelocytes* The neutrophilic leukocytes, in smears and sections of blood and bone marrow of all species investigated, reacted strongly with the periodic acid-Schiff reagents (fig 1b). The antecedent neutrophilic metamyelocytes and myelocytes also reacted positively, the amount of reactive substance being minimal in the myelocytes and increasing as the cells mature into leukocytes. The reaction in the neutrophilic series was completely absent after preliminary use of saliva, indicating that glycogen was responsible for it. Although the glycogen seemed to occur in the cytoplasm in granular or punctate form, it did not appear to be actually localized in the neutrophilic granules, for, as in other

- j A typical lymphocyte from a case of chronic lymphatic leukemia showing the maximal number of stained cytoplasmic bodies

FIG. 1

glycogen-bearing cells, it frequently shifted with fixation to one side of the cell (fig 1b)

*Lymphocytes* The lymphocytes of human peripheral blood were for the most part negative, but about 1 in 10 showed a few deep red Schiff-positive cytoplasmic granules which did not seem to be soluble in saliva. In smears from several patients with chronic lymphatic leukemia, the number of lymphocytes showing these granules was both relatively and absolutely increased. In one case, practically all of the lymphocytes contained from 6 to 12 bright red dots (fig 1j)

The cytoplasm of the lymphocytes observed in stained sections of the spleen and lymph glands of the rhesus monkey was negative

*Monocytes* In smears of human peripheral blood these cells exhibited pale pink, diffuse cytoplasmic staining which did not seem to be influenced by saliva. It was our impression from comparing the staining observed in the various cells of blood and bone marrow that this faint staining of the monocytes was a nonspecific reaction

*Megakaryocytes* In sections of monkey bone marrow these cells exhibited a multitude of indistinct, dustlike, reddish particles located in more faintly stained cytoplasm. This staining was not affected by preliminary treatment with saliva (fig 1g)

In sections of human bone marrow the megakaryocytes exhibited somewhat more intense staining. The diffusely pink cytoplasm contained uneven sized, irregularly scattered, red particles. After treatment with saliva, the red material was no longer visible although the pink background tone survived (figs 1h and i)

In the bone marrow of the rabbit the megakaryocytes stained more intensely than in either monkey or man. Larger red particles filled a good portion of the cells, appearing against a finely punctate reddish background (fig 1f). Treatment with saliva diminished this staining but by no means abolished it.

*Platelets* These were only examined in human peripheral blood. The platelets showed a fine red stippling similar to that seen in the megakaryocytes (fig 1h). This staining failed to occur after exposure to saliva (fig 1i)

### DISCUSSION

*Comparison of saliva and malt diastase* Malt diastase was briefly compared with saliva in reference to its effect on the periodic acid-Schiff reaction and the identification of glycogen. Diastase was tested on several sections of monkey's and rabbit's bone marrow in which neutrophilic leukocytes, neutrophilic myelocytes, eosinophils and megakaryocytes were readily identifiable. Similar to saliva, the use of diastase prevented completely the staining of neutrophilic leukocytes and their myelocytic precursors, but, unlike saliva, it reduced very markedly the staining of both eosinophils and megakaryocytes. These results indicated that saliva and the preparation of malt diastase employed were not completely identical in their action. The latter attacked a wider range of substances than saliva. In connection with other studies we have observed that malt diastase is capable of preventing the staining of basement membranes and reticulum by the periodic acid-Schiff method.

*The nature of the periodic acid-Schiff reaction in blood cells* The action of periodic

acid depends on the oxidation of carbohydrate compounds. As a result, aldehydes are formed and these are revealed by their colored reaction with the leukofuchsin of Schiff's reagent. The reaction produced in some types of blood cells by this technic appears to be due to glycogen, but in other blood cells the saliva-resistant substances which stain must contain other kinds of carbohydrates. In the case of the neutrophilic leukocytes and their myelocytic precursors, the stained substance is undoubtedly glycogen in all species examined. In man the megakaryocytes and platelets also appear to contain glycogen. In the monkey, on the contrary, the megakaryocytes are stained but the substance involved does not seem to be soluble in saliva.

It is well established that the periodic acid-Schiff reaction occurs with a variety of acid mucopolysaccharides (particularly epithelial mucus), and it is probable that the reaction is associated with the carbohydrate fraction of these substances. In mast cells, which possess granules containing an acid mucopolysaccharide, the positive reaction may well be explained in such a way. Species differences exist in the staining of mast cells by the periodic acid-Schiff reagents, in man and monkey their granules stain quite intensely, whereas in the rat they are at best very faintly differentiated. This variability suggests species differences in the availability of the carbohydrate radicals. In this connection it is of interest to note that the intense metachromatic staining of the mast cell granules with toluidin blue shows no such species variability. However, metachromatic staining depends upon the presence of sulphate groups rather than upon the carbohydrate moieties of mucopolysaccharides.

Concerning basophilic leukocytes, there is little that we can say at present. The occasional basophils, encountered in normal blood smears of human blood, contain numerous small red dots in their cytoplasm. The fact that we have not identified any similarly stained cells in several smears exposed to saliva suggests that these droplets consist of glycogen. Yet, these findings seem too few to establish this point definitely. If the above result proves to be consistent, it would indicate a difference in the histochemical composition of mast cells and basophilic leukocytes.

In a previous investigation of the blood cells of the rhesus monkey by the Bauer-Feulgen method, Wislocki and Dempsey<sup>6</sup> observed that only the polymorphonuclear neutrophils and their metamyelocyte precursors gave a positive reaction, and this staining was shown to be due to glycogen. Subsequently, Rheingold and Wislocki<sup>7</sup> described the megakaryocytes of human marrow as giving a faint Bauer-Feulgen reaction in contrast to the negative megakaryocytes of the rhesus monkey. Comparison of these previous findings with the present ones indicates that the Bauer-Feulgen technic, as we have carried it out, is not as sensitive as the periodic acid-Schiff reaction. Regardless, however, of the fact that the two methods have not been quantitatively alike, as we have used them, they have corroborated one another in indicating that there are histochemical differences between the megakaryocytes of man and rhesus monkey.

The reaction in the several types of eosinophils does not appear to be due to glycogen. Nor can it be possibly ascribed to an acid mucopolysaccharide when one

considers the fact that the cytoplasm of these cells is alkaline in nature. It is conceivable that it might be attributable to the presence of a neutral mucopolysaccharide. Noteworthy also is the observation that, whereas in the eosinophils of the bone marrow of rabbit and monkey it is principally the granules which are stained, in the eosinophils of human peripheral blood it is the cytoplasmic ground substance which is chiefly colored.

### SUMMARY

An account is given of the periodic acid-Schiff reaction in the cytoplasm of various normal cells of blood and connective tissue of man, rhesus monkey and rabbit. Saliva treated control sections were used to distinguish glycogen from other reactive substances. The effects of malt diastase were compared briefly with those of saliva. The results of the present study may be summarized as follows (table 1).

TABLE 1—*Brief characterization of the cytoplasmic staining of various cells of blood and connective tissue by the periodic acid Schiff method with saliva controls*

Glyc = Positive reaction due to glycogen. Pos. = Positive reaction presumably due to other carbohydrates. Ft = Faint and questionable reaction, Neg = No reaction. \* = Not crucially tested with saliva. † = Normally positive in about 1 cell out of 10. Blank spaces indicate that no observations were made.

## GLYCOGEN IN HUMAN BLOOD CELLS

By ROBERT P GIBB, M D \* AND ROBERT E STOWELL, M D

NEW IMPROVED histochemical technics for detecting glycogen in tissues justify reinvestigation of the distribution of glycogen in human blood cells. Histochemical methods permit more precise observations on the localization of glycogen within single cells of different types than are obtained by macrochemical analyses. Most investigators have claimed that glycogen is present in only certain types of white blood cells. The application of improved technics should yield facts permitting a better understanding of the metabolism and functions of normal and abnormal cells. In his recent review of the functions of leukocytes, Rebuck<sup>1</sup> emphasizes the contributions which histochemical studies have already made to the advancement of our knowledge of leukocytic function. Furthermore, histochemical technics should also be explored for possibilities in providing improved methods for diagnosis of disease in which morphologic differences in blood cells are not easily distinguished.

Therefore, the Gomori<sup>2</sup> and the Hotchkiss<sup>3</sup> technics for demonstrating glycogen have been applied to the study of glycogen in normal and abnormal peripheral blood and bone marrow. The results were compared with those obtained by other histochemical and by macrochemical methods in this and other laboratories.

Neukirch<sup>4</sup> in 1910 noted granular material in polymorphonuclear neutrophiles which were stained by iodine and Best's carmine. He attributed these granules either to glycogen or some closely related carbohydrate. In platelets a centrally located granule was stained by Best's carmine, but this was not removed by salivary digestion. Iodophilic granules were described in myeloid cells, lymphocytes, platelets, and megakaryocytes by Stahl, Horstmann, and Hilsnitz in 1925.<sup>5</sup> In 1941, histochemical studies of blood glycogen by Mancini and Celani Barry<sup>6</sup> compared the results of the Bauer-Feulgen technic with the iodine and Best's carmine methods on dried blood films. Glycogen-positive granules were described in cells of the myeloid series. Polymorphonuclear neutrophiles produced the most intense reactions. Altmann-Gersh freezing fixation revealed larger quantities and more regular distribution of glycogen than did chemical fixation.<sup>7</sup> Lymphocytes and monocytes in all blood films studied in man and in corresponding cells of other animals were not observed to contain glycogen. Using paraffin sections of peripheral blood and hemopoietic tissue stained with Bauer-Feulgen and Mitchel and Wislocki's<sup>8</sup> ammoniacal silver technics, Wislocki and Dempsey<sup>9</sup> in 1946 observed glycogen in neutrophilic leukocytes but not in other blood cells, megakaryocytes, or blood platelets. In these investigations absence of the reactions in control films or sections exposed to salivary digestion prior to staining was proof that glycogen was the substance demonstrated.

## MATERIALS AND METHODS

Peripheral blood and bone marrow films were prepared on chemically clean cover glasses and were air-dried and stored for periods of a few days to four months before staining. Storage for periods longer than four months usually resulted in a diffuse precipitation on the films during staining but did not significantly alter cellular glycogen content. Just prior to staining the films were fixed in absolute alcohol from one to two minutes, dipped in 95 per cent ethyl alcohol, and placed in 50 per cent ethyl alcohol for two or three minutes. Coating films with celloidin was found to be unnecessary.

The first method used to stain glycogen was the chromic acid-silver methenamine technique described by Gomori.<sup>2</sup> The oxidation of the glycogen with liberation of free aldehyde groups produced a localizing black deposit of reduced metallic silver. Aqueous safranin was used as counterstain.

The second technique employed was developed by Hotchkiss<sup>3</sup> and differs from that described by McManus<sup>10</sup> and by Lillie<sup>11, 12</sup> in that a periodic acid solution buffered with sodium acetate was used to liberate the free aldehyde groups from the glycogen molecule. The films were counterstained with a basic dye using either methylene blue, light green, or toluidin blue. Glycogen stained reddish purple.

A few films were treated with the Bauer Feulgen<sup>13</sup> technique for comparison of results. Control films exposed forty-five minutes to salivary digestion were prepared with each group of films and each technique.

Peripheral blood films were examined on 9 normal subjects. Morphologically normal peripheral blood (12\*) and bone marrow films (11) were studied from patients with carcinoma (5), Laennec's cirrhosis (3), thyrotoxicosis (3), myxedema, nutritional deficiencies, syphilis, Hodgkin's disease, Addison's disease, and hepatolenticular degeneration (Wilson's disease). Peripheral blood films were also examined from patients with a variety of blood conditions including lymphoid leukemia (9), leukocytosis (8), myeloid leukemia (3), infectious mononucleosis (3), mycosis fungoides with eosinophilia (2), aplastic anemia (2), hypoglycemic shock (2), leukopenia (2), and one case each of monoblastic leukemia, monocytic leukemia, polycythemia, thrombocytopenic purpura, hemophilia, pertussis with lymphocytosis, hypoplastic anemia, and hemolytic anemia. Bone marrow films were examined from patients with polycythemia (7), lymphoid leukemia (5), pernicious anemia (5), hypoplastic anemia (4), myeloid leukemia (2), multiple myeloma (2), and one case each of monoblastic leukemia, reticulum cell sarcoma, thrombocytopenic purpura, agnogenic myeloid metaplasia, leukemoid blood picture, mycosis fungoides with eosinophilia, strongyloidiasis with secondary anemia, and hemolytic anemia †.

Macrochemical determinations of whole blood were made on the fasting blood of two normal people and 2 patients with lymphatic leukemia. The technique employed was essentially that described by Good, Kramer, and Somogyi<sup>14</sup> with slight modifications. Following hydrolysis, glucose was determined by the method described by Nelson<sup>15</sup> using the Klett-Summerson photoelectric colorimeter. Yeast-fermented controls were also run. Similar glycogen determinations on leukocytes on the buffy coat of centrifuged blood were less satisfactory.

## RESULTS

The silver reduction method of Gomori and periodic acid fuchsin sulfite method of Hotchkiss produced essentially the same results on normal blood films. When present in small amounts, glycogen was more readily observed by the silver method because of the sharp contrast produced by the black precipitate. For this reason, this technique was preferred for the study and photography of the cells. Because of the nonspecific tinting of the films which occurs with the Bauer Feulgen technique, it was difficult to study and evaluate the presence or absence of small amounts of glycogen. Where larger amounts of polysaccharide were present, the results did not differ significantly from those obtained with the Gomori and Hotchkiss techniques. Diffuse tinting of extracellular material was observed with the Hotchkiss

\* The number enclosed in parenthesis is the number of normal subjects or patients studied.

† Appreciation is expressed to Dr. Carl V. Moore, Department of Medicine, Washington University School of Medicine for facilitating the obtaining of the clinical material.

technic only in very thick areas of bone marrow films. Otherwise the reaction was strictly localized in the cellular cytoplasm. Light green or toluidin blue counterstain aided visualization of small quantities of glycogen in both the Bauer-Feulgen and Hotchkiss technics.

*Normal subjects* Using the technics described, erythrocytes, normoblasts, and erythroblasts of normal blood and bone marrow did not reveal detectable amounts of glycogen. Megaloblasts\* were not identified in the normal films. All myeloid cells contained significant amounts of glycogen with the Hotchkiss and Gomori technics. Segmented polymorphonuclear leukocytes were most intensely stained while the glycogen was decreased in the younger cells as exemplified in figures 1 and 2. Not only was there a diminution in the total amount of glycogen corresponding to the decrease in cytoplasm in these younger cells, but there was also a lower glycogen concentration as manifested by a reduced intensity of the histochemical reactions. Individual identification and classification of the younger myeloid elements was not possible, but, by comparison of percentiles of various types and rough morphologic comparison of films of the same marrow stained with Wright's stain, it was possible to conclude that cells as young as the myelocyte. C neutrophils contained moderate amounts of glycogen and younger cells probably contained at least slight amounts. All identifiable myeloid cells contained significantly detectable amounts of glycogen. In the young cells the glycogen was present in a finely granular form evenly distributed throughout the scant cytoplasm. We attempted to evaluate quantitative differences in individual polymorphonuclear neutrophils. After considering cell maturity, cell size, differences of intensity for a given film and for a given area of the film being studied, it was difficult to appreciate significant alterations in the quantities of glycogen in the individual cells of a given age. Using the Gomori technic, differences were noted in the form and distribution of cytoplasmic granules of mature polymorphonuclear neutrophils. The glycogen was usually distributed as an almost solid, dense cytoplasmic conglomeration of granules. These were frequently so numerous that they overlay portions of the nucleus, not uncommonly obscuring most of it. Occasionally the granules were more diffuse in distribution and finer in structure. This produced a gray coloration to the cytoplasm rather than the jet black which was most commonly observed. Dense homogenous appearing clumps of glycogen were occasionally present with the smaller more diffuse distribution of granules. These differences were not apparent by the Hotchkiss or Bauer-Feulgen technics.

Eosinophilic leukocytes were easily identified in the silver stained films by their typical large granules and as is shown in figure 5 were silhouetted in bold relief against a black background of cytoplasmic silver stained glycogen. Eosinophilic myelocytes in the bone marrow likewise contained glycogen, but in reduced amounts as described for neutrophilic myelocytes. These granules were also visualized by the Hotchkiss and Bauer-Feulgen methods, but were not outlined as clearly. Basophilic leukocytes were not identified.

All lymphocytes observed in films stained deeply with the Gomori technic con-

FIG 4—Three lymphocytes and a platelet containing small amounts of glycogen, lymphoid leukemia bone marrow ( $\times 1215$ ).

FIG 5—Eosinophilic leukocyte shown in Fig 1 revealing eosinophilic granules and extragranular glycogen ( $\times 1215$ ).

FIG 6—Polymorphonuclear leukocyte, myelocyte A and blast cells showing small amounts of cytoplasmic glycogen, peripheral blood of patient with acute myeloid leukemia ( $\times 1215$ ).

FIG 7—Lymphocytes and polymorphonuclear neutrophils showing removal of glycogen by saliva digestion before staining, strongly counterstained, lymphoid leukemia bone marrow. Same marrow as Fig 4 ( $\times 1215$ ).

tained glycogen. The amounts were small and produced a thin black rim of granules around the relatively large nucleus as shown in figure 1. Occasionally the glycogen of the lymphocytes was manifest as a few large granules located in areas where the cytoplasm was greatest in amount. The quantity of glycogen varied directly with the amount of cytoplasm visible. The larger and presumably younger cells contained, therefore, more glycogen. The Hotchkiss method revealed glycogen in almost all lymphocytes. With the Bauer-Feulgen technic glycogen granules were present in a few lymphocytes.

All monocytes contained a moderate amount of glycogen, more diffusely distributed and superimposed over portions of the nucleus and characterized by smaller granules than those of the polymorphonuclear neutrophils. The carbohydrate was demonstrable by all three technics.

The three methods employed revealed glycogen in both megakaryocytes and platelets. In both of these elements the polysaccharide appeared in two forms as can be seen in figures 1, 3, 4, 8 and 9. A finely granular form was diffusely distributed in the cytoplasm and over parts of the nucleus in megakaryocytes and was present in the peripheral portion of the platelets. In the majority of the megakaryocytes deeply staining homogenous appearing clumps of glycogen overlay a large part of the nucleus, and in the platelets a similarly deeply staining centrally located clump was present (fig. 3). Occasionally parts of this homogenous substance in the megakaryocytes stained a deep brown color and blended smoothly into the adjacent black material. The amount varied from a few small granules to a large clump or clumps of glycogen occupying about two-thirds of the cell.

*Myeloid Leukemia* Leukemic myeloid cells did not differ significantly from cells of similar age and size seen in normal peripheral blood and bone marrow. The leukocytes observed in the peripheral blood of one patient containing 71 per cent myelocyte A cells and 12 per cent myeloblasts showed significant quantities of glycogen. Figure 6 shows that the glycogen in these young cells was small in amount and uniformly distributed as fine granules in the thin rim of cytoplasm. Other formed elements of the blood did not differ significantly in glycogen content from similar elements in normal blood and bone marrow.

*Lymphoid Leukemia* In adequately stained films leukemic lymphocytes contained glycogen. The small amount was frequently evident as a few cytoplasmic granules as shown in figure 4. These cells vary in the speed of their response to the silver-methenamine reaction. In weakly stained preparations up to one-half of the lymphocytes showed negative reactions. In duplicate films stained for longer periods of time all lymphocytes observed contained detectable granules. Myeloid cells, monocytes, and platelets when present contained glycogen granules in amounts which did not differ significantly from those observed in the normal.

*Monoblastic Leukemia and Monocytic Leukemia* Leukemic monocytes contained a moderate amount of glycogen similar in distribution to that seen in monocytes in

FIG. 9.—Segmented polymorphonuclear neutrophils showing dense concentrations of glycogen and a platelet with a small amount of glycogen. bone marrow of patient with polycythemia ( $\times 1,215$ )

normal blood films Monoblasts in the bone marrow and peripheral blood of a patient with monoblastic leukemia contained a few granules of glycogen in the cytoplasm These monoblasts constituted 99 and 94 per cent of the leukocytes in the bone marrow and peripheral blood films respectively

*Multiple Myeloma* Myeloma cells were identified in the bone marrow of two patients with this disease One film contained 71 per cent and the other 18 per cent myeloma cells As shown in figure 8 the abundant cytoplasm of these cells contained glycogen in a moderately fine granular form These patients had not been treated with stilbamidine and cytoplasmic inclusion bodies of the type described by Snapper<sup>16</sup> were not present in films stained with Wright's stain Glycogen in leukocytes in films from patients with multiple myeloma did not differ significantly from that observed in similar cells of normal bone marrow

*Infectious Mononucleosis* With the stains employed, it was not always possible to differentiate with certainty between the cells of infectious mononucleosis, monocytes, and large lymphocytes Glycogen was not visualized in large cells morphologically similar to the characteristic cell of infectious mononucleosis Other cells similar in appearance but presumed to be large lymphocytes or monocytes contained slight to moderate amounts of glycogen

D1	74,850	3.19	0.11

*Polycythemia* Polymorphonuclear cells from patients with polycythemia stain intensely Dense homogenous-appearing cytoplasmic clumps of glycogen similar in appearance to those in the normal were present in large amounts in mature polymorphonuclear leukocytes as shown in figure 9 Platelets and megakaryocytes reacted strongly The quantity of glycogen in lymphocytes and monocytes did not differ significantly from that described in normal cells

*Other conditions* The formed blood elements from the peripheral blood and bone marrow of the sampling of patients with leukocytosis, leukopenia, the anemias, hypoglycemia, diabetes, thyrotoxicosis, myxedema, Addison's disease, cirrhosis, thrombocytopenic purpura, hemophilia, carcinoma, reticulum cell sarcoma, Hodgkin's disease, agnogenic myeloid metaplasia, mycosis fungoides, syphilis, and pertussis contained amounts of glycogen which did not differ appreciably from similar cells in normal films Abnormal cells were not identified in the bone marrow films of reticulum cell sarcoma or carcinoma

Saliva completely removed the glycogen from myeloid, lymphoid, monocytic and plasma cells, and platelets and megakaryocytes as evidenced by the absence of reaction with the histochemical technics employed. Figure 7 illustrates this removal of glycogen in lymphocytes and a segmented polymorphonuclear neutrophil in the bone marrow from a patient with lymphoid leukemia.

The results of macrochemical glycogen analysis of whole blood and buffy coat are summarized in table I. Blood from patients with lymphoid leukemia, C<sub>1</sub> and D<sub>1</sub>, had differential counts of 4, 96, 0 and 2, 97, and 1 per cent polymorphonuclear leukocytes, lymphocytes, and monocytes respectively while the mean percentages for the normals was 72, 18, and 10. Significant glycogen values of 10.47 mg per cent and 3.19 mg per cent were obtained in two cases of lymphoid leukemia. Following yeast fermentation only traces of nonfermentable reducing substances were present. These did not significantly alter the glycogen values obtained.

### DISCUSSION

The histochemical demonstration of greater quantities of glycogen than has been previously reported may be attributed in part to the greater sensitivity of the histochemical methods used in this study. Gomori<sup>2</sup> has adequately discussed the features of his technic which increase the sensitivity over the Bauer-Feulgen and the Mitchel and Wislocki ammoniacal silver technics. The increased sensitivity of the Hotchkiss method may be due to the fuchsin-sulfite which is decolorized and cleared with charcoal to eliminate the diffuse tinting that obscures small quantities of the carbohydrate in the Bauer-Feulgen method. Because of the marked contrast which the black reduced silver produced in blood films, the Gomori technic is superior for the detection of minute quantities of glycogen in blood cells.

The demonstration of greater quantities of glycogen may also be attributed in part to the use of blood films rather than tissues prepared by histological methods. Although glycogen does have a low solubility in alcohol solutions, a small loss is to be expected by washing in the large number of solutions which are required for the preparation of histologic sections. Even though these have been reduced to a minimum in the methods used, it is not improbable that some loss of glycogen still occurs. K. H. Meyer<sup>17</sup> has pointed out that glycogen exists in varying degrees of polymerization and the greater the degree of polymerization the less water soluble is the glycogen. On a theoretic basis the low polymer molecules which are the most readily lost would also be the most difficult to demonstrate histochemically for the concentration of potentially free aldehyde groups would not be as great. These aldehyde groups are located between carbon atoms with free hydroxyl groups and their concentration would be proportional to the number of polymerized glucose radicals. As Hotchkiss<sup>2</sup> emphasizes, low molecular compounds such as simple sugars, hydroxyamino acids with adjacent hydroxyl and amino radicals and substituted inositol compounds can react with the periodic acid reagent, but these are not normally present in fixed preparations. The pentose component of nucleic acids is so substituted that it does not react with periodic acid. Cerebrosides would be expected to react if they were retained in the preparations. Hotchkiss believes that the principal substances which would be expected to show the periodic acid fuchsin sulfite stain in animal tissues are glycogen, mucin, mucoprotein, and presumably hyaluronic acid and chitin. Lillie has shown that acidi-

fied sodium periodate solution will also react with collagen, reticulum and fibrin <sup>11, 12</sup> The use of salivary digestion of control tissues should permit the reasonably definite identification of glycogen with these technics

This discussion has so far ignored the results obtained using iodine stains The chemistry of this reaction is poorly understood and most investigators believe that iodine is usually more non-specific and produces more diffuse tinting than does the Bauer-Feulgen technic Mancini and Celani Barry<sup>6</sup> do not share this opinion and have based their conclusions chiefly on observations employing iodine staining of blood films They did observe greater quantities of glycogen in neutrophilic leukocytes than workers using tissue sections prepared by histologic methods, but were not able to observe the small quantities of glycogen in other blood cells It seems probable that these small quantities of glycogen may be obscured by the diffuse tinting which iodine produces The iodophile granules observed by Stahl, Horstmann, and Hilsnitz<sup>5</sup> in neutrophils, lymphocytes, platelets, and megakaryocytes were most likely glycogen granules Their observations have now been confirmed by three histochemical methods, with absence of staining in respective control sections The present observations do not agree with the findings of Stahl, Horstmann and Hilsnitz that glycogen appears in erythroblasts and increases with progressive maturity of these cells The bronze coloration which iodine produces in erythroid cells parallels the appearance of, and increases with increasing hemoglobin content and might be interpreted more as a reaction with hemoglobin than with glycogen Although glycogen in erythrocytes has been reported by Ellis and Payne<sup>18</sup> using macrochemical methods it has been denied by many other workers (Bridge and Holt,<sup>19</sup> Van Creveld,<sup>20</sup> Wagner<sup>21</sup>)

These observations of glycogen in cells of the myeloid series are in full agreement with the work of Mancini and Celani Barry<sup>6</sup> They do not mention eosinophilic leukocytes specifically, but may have included them in their general term myeloid cells Wislocki and Dempsey<sup>9</sup> reported glycogen in neutrophilic leukocytes but were unable to identify eosinophilic leukocytes with certainty in their preparations Eosinophilic leukocytes were identified in our preparations (fig 4), but not basophilic leukocytes Because myeloid cells which were free from glycogen were not observed in normal peripheral blood and bone marrow films, basophiles, although not specifically identified, may also contain glycogen

Because of the intense reactions occurring in the mature polymorphonuclear neutrophils with all three technics, it was not possible to demonstrate azurophilic or neutrophilic granules in the glycogen preparations The glycogen was present in younger cells than those containing neutrophilic granules in Wright's stained films It was present in larger amounts than might be accounted for if present only in azurophilic granules Granules of glycogen were in all cases larger in size than neutrophilic granules of films stained with Wright's stain The carbohydrate was also present in eosinophilic leukocytes, plasma cells, platelets, and megakaryocytes which do not contain neutrophilic or azurophilic granules Eosinophilic granules were definitely outlined by the cytoplasmic glycogen Therefore, it cannot be concluded that glycogen is a component of neutrophilic, azurophilic or

eosinophilic granules, rather, it is believed that the glycogen is contained in the extra granular cytoplasm.

Wright's postulated origin of platelets from megakaryocytes<sup>22</sup> is further substantiated by the histochemical demonstration of glycogen in two morphologically similar forms in both elements. As visualized in figure 3 the formation of platelets from the periphery of the megakaryocytes is evident in the preparations.

Contrary to the observations of previous workers, moderate amounts of glycogen in monocytes, and small amounts of glycogen in lymphocytes were observed and were demonstrated by three different methods. This glycogen was also removed by salivary digestion. The glycogen of leukemic myeloid monocytic, and lymphoid cells did not differ significantly in amount and distribution from normal cells of the same stage of maturation. It was not possible to demonstrate a histochemical difference in the content of glycogen in leukemic myeloblast and monoblast cells.

The glycogen content of myeloma cells to our knowledge has not been previously reported. It will be of interest to compare the glycogen content of normal plasma cells with the myeloma cells.

The dense homogenous clumps of glycogen which were observed in the polymorphonuclear leukocytes of polycythemia were suggestive of increased glycogen in these cells. Because of the intense reactions which also occur in the normal, it was difficult to interpret the significance of this apparent increase. Platelets and megakaryocytes also reacted strongly. Wagner<sup>22</sup> has reported an increase in the glycogen content of whole blood and in isolated leukocytes in this disease as determined by macrochemical methods.

Large mononuclear cells which did not contain glycogen were observed in blood films of three patients with infectious mononucleosis. These cells could not be differentiated with certainty from monocytes and large lymphocytes, both of which are also increased in the blood of patients with this disease. Monocytes and lymphocytes in the blood of normal subjects and patients with other diseases contain glycogen. These large mononuclear cells were the only leukocytes observed in this study which did not contain glycogen.

The demonstration of glycogen in lymphocytes and platelets does not agree with the results of macrochemical determinations by Wagner.<sup>21, 22</sup> From studies of whole blood and isolated buffy coat leukocytes from normal individuals and from patients with different types of leukemias, he concluded that the granular leukocyte is the only carrier of glycogen in whole blood. He also stated that lymphocytes, blast cells, and platelets do not contain any measurable amounts of glycogen. The experience obtained in the present study with a method of glycogen determinations comparable to that employed by Wagner corroborates his findings, that the values obtained would not indicate a significantly measurable amount of glycogen in lymphocytes. It should be stressed, however, that the wide variations in normal values which he obtained, 1.2 to 16.2 mg per cent in 42 determinations on 28 normal individuals, might indicate a wide range of error in the method. Wagner found 10.9 mg per cent and 14.4 mg per cent whole blood glycogen in two patients with chronic lymphatic leukemia and blood differential counts show-

ing 100 per cent lymphocytes. Although these glycogen values are within the normal range and might be attributed to granular leukocytes present in quantities less than 1 per cent of the differential picture, the slight increase in glycogen could well be correlated with the increased number of lymphocytes. Only a more extensive study of the glycogen content of the blood of patients with lymphatic leukemia would reveal if this is a significant increase. The authors believe that the methods now available for the macrochemical determinations of glycogen are not sufficiently delicate to quantitatively measure this substance in the small amounts which are demonstrable histochemically. It is evident that the number of lymphocytes (fig. 4), platelets (figs. 1 and 3), or blast cells (fig. 6) which would contain the equivalent of the amount of glycogen present in one polymorphonuclear leukocyte is very large, possibly a hundred or more.

### CONCLUSIONS

Three different histochemical methods were applied to the study of glycogen in normal and abnormal peripheral blood and bone marrow films. The techniques employed were the chromic acid-silver-methanamine procedure of Gomori, the periodic acid-fuchsin-sulfurous acid technic of Hotchkiss and the Bauer-Feulgen stain. Control sections were treated with saliva to remove the glycogen.

Large amounts of glycogen were demonstrated in the cytoplasm of polymorphonuclear, metamyelocytic, and myelocytic neutrophilic leukocytes and in the extra granular cytoplasm of eosinophilic leukocytes in films from normal individuals. Megakaryocytes and the cytoplasm of monocytes contained moderate amounts of glycogen, and platelets and the cytoplasm of lymphocytes smaller amounts.

Examination of peripheral blood and bone marrow of patients with a variety of hematologic, metabolic, and infectious diseases failed to reveal significant differences in glycogen content from the normal with the possible exception of polycythemia in which a suggestive increase in cellular glycogen was observed in polymorphonuclear leukocytes, platelets, and megakaryocytes. A moderate amount of glycogen was observed in multiple myeloma cells. Large cells in patients with infectious mononucleosis did not stain for glycogen.

# A HISTOCHEMICAL STUDY OF ACID AND ALKALINE PHOSPHATASE DISTRIBUTION IN NORMAL HUMAN BONE MARROW SMEARS

By M. RABINOVITCH AND D. ANDREUCCI, M.D.

**A**LKALINE phosphatase activity was studied histochemically in normal and abnormal human blood and bone marrow smears (Wachstein<sup>1</sup>) after covering them with an alcohol-ether-celloidin solution for a few seconds. In a preliminary note we<sup>2</sup> reported the distribution of acid phosphatase in bone marrow smears after fixation in chilled acetone. Rheingold and Wislocki<sup>3</sup> reported on the localization of both phosphatases in smears and imprints of bone marrow after fixation in chilled 80 per cent alcohol. Preliminary work to determine the best fixation procedure led us to the conclusion that formol-vapor gives the best cytological preservation for both phosphatase techniques. In this paper we describe the distribution pattern of both phosphatases in normal human bone marrow smears using this method of fixation.

## MATERIALS AND METHODS

Bone marrow smears were obtained by sternal puncture from 17 normal pregnant women and 3 adult men without hematologic disorders. The smears were made on slides, rapidly dried in air and stored in a sulphuric acid desiccator until the time for fixation. In most instances they were subjected to the phosphatase methods 2-3 days after this puncture.<sup>4</sup> 15-30 day old slides yielded the same results but after two months storage a distinct reduction in activity was observed especially of the acid phosphatase activity. The methods used were those reported by Gomori<sup>5</sup> but somewhat modified by Wachstein<sup>1</sup> and ourselves.<sup>2</sup>

For the alkaline phosphatase technic the following incubation mixture was used: water, 10 ml, 6 per cent barbital buffer (pH 9.0-9.5), 5 ml, 2 per cent sodium glycerophosphate (50 per cent alfa May and Baker), 2 ml, 2 per cent calcium nitrate, 2 ml, and 1 ml of a 0.1 per cent magnesium sulphate solution. Slides were incubated from 10 to 20 hours at 37°C, then treated according to Wachstein<sup>1</sup> with due consideration for the critical timing studied by Danielli.<sup>6</sup> Controls were run by omitting the glycerophosphate solution from the incubation mixture.

For the acid technic the incubation mixture, treatment and controls were the same as those referred to in our previous note.<sup>2</sup> Incubation periods were from 10 to 20 hours or more. Incubation at pH 5.2 gave the same results as at pH 4.2. Dilution of the incubation mixture (2 or 1:4) did not interfere with the results.

**Choice of fixatives.** The following fixatives produced an intense or total inactivation of both phosphatases after incubation for 10 hours: Osmic acid vapor for 2 minutes then wash for 30 seconds; Bouin's solution for 30 minutes then wash 15 minutes; methyl alcohol for 4 minutes then wash 30 seconds. The following fixation methods preserved activity of both phosphatases: acetone at 4°C for 30 seconds then wash a few seconds; treatment according to Wachstein<sup>1</sup>; 10 per cent formol saline for 15 minutes then wash for 15 minutes; formol vapor for 3 minutes at 44°C, then wash in running water for 15 minutes; †, ‡, §.

From the Department of Obstetrics and Department of Histology and Embryology, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil.

\* Smears fixed 15 minutes, 5, 12 or 14 hours after the puncture yielded the same results.

† Washing for 100 minutes under the tap did not alter the results.

‡ Fixation for 10 minutes resulted in distinct inhibition of enzymatic activity especially of the alkaline enzyme. In the later stages of this investigation, 5 min. fixation was used for the acid technic; the greater inactivation so produced was counteracted by extension of the incubation period.

§ Fixation in a closed vertical Coplin jar containing a few drops of neutralized formaldehyde.

In addition to these 1 per cent formol in 50 per cent alcohol for 5 minutes then wash for 15 minutes and alcohol sublimate (1 part absolute alcohol and 1 part saturated aqueous sublimate solution) for 30 minutes then wash for 15 minutes inactivated the acid but partly preserved the alkaline phosphatase reaction

Ten per cent formol saline best preserved the enzyme activity of both phosphatases. The most satisfactory cytologic preservation in both methods was obtained by means of the formol vapor fixation and it was therefore the fixation procedure used throughout this study.

The photomicrographs were obtained from the richest and best preserved smears from cells whose nuclear pattern most nearly approached that obtained by means of the best fixation procedures with the usual hematologic stains. They do not therefore represent the commonest pattern observed.

The terminology used is that of Ferrata,<sup>7</sup> slightly modified with regard to the red cell series, in which we considered early and late erythroblasts.

## OBSERVATIONS

### *Acid Phosphatase*

About 240 slides were studied and of these 110 had been fixed by means of formol vapor. On the latter, 70 were considered good ones. Slides from each case were incubated on at least two different occasions.

*General data.* An evident correlation between the intensity of the reaction and cellular richness of the marrow material was found, but slight qualitative differences between slides were also observed. In some of the slides a dark extracellular precipitate occurred, which did not disturb the examination of the smears. The background in smears fixed by formol saline or formol vapor remained unstained, but after acetone fixation or Wachstein's treatment, it assumed a brownish color (extracted enzyme?). With incubation periods of about 10 hours the structures positive for acid phosphatase were distinctly stained and extension of the incubation periods (up to 33 hours, for instance) brought only a deeper stain, the qualitative picture remaining the same (see fig. 12).

Nuclear pattern generally approached that obtained with hematologic stains and Feulgen's method, and in the best preserved smears conformed almost exactly to that pattern. When this occurred, a negative ground cytoplasmic reaction was observed in the granulocytic and in part of the red cell series. These were considered the most reliable acid phosphatase reaction pictures. We therefore will not describe the nuclear pattern of the best preserved smears. The intensity of the nuclear stain of the granulocytic and red cell series increased as maturation occurred parallel to what is observed with the Feulgen reaction.

Nonspecific granules were negative, appearing on the nuclei of immature cells (figs. 1, 2, 3). \* Specific neutrophilic (figs. 2, 3) and eosinophilic granules (fig. 4) reacted, although the former presented a variation in number and intensity of

\* The nonspecific granules referred to here are light areas in the basophilic cytoplasm over the nuclear area and beyond the nuclear membrane as seen in dry smears. They represent the negative images of cytoplasmic organoids—chiefly mitochondria. Depending upon their location they contribute to what hematologists have called hyaloplasm and parachromatin (See Jones O. P. Blood 3: 967, 1948). In a personal communication from M. Rabinovitch he more or less agrees with this interpretation. It seems that the term nonspecific granule should not be used for the negative images of organoids because the various aurophilic granules have been considered as nonspecific in contrast to the specific granules.

*Ed. O. P. J.*

staining This variation was observed only in material fixed by formol vapor, and in this particular case we could not blame fixation time, incubation period, or the intensity of the reaction

FIGS. 1-12.—PHOTOMICROGRAPHS OF HUMAN MARROW SMEARS AFTER ACID PHOSPHATASE REACTION Magnification 1940 diameters excepting figures 1 and 2 which are 1200 diameters Reduction about  $\frac{1}{3}$  off Fig 1—Promyelocytes with negative images of organoids over nucleus Reaction of neutrophilic granules is almost absent Fig 2—Neutrophilic promyelocyte with positive reaction of specific granules and negative images of organoids Fig 3—Neutrophilic promyelocyte and two segmented forms with positive specific granules and negative images of organoids Three erythroblasts with strongly positive nuclei Fig 4—Eosinophilic promyelocyte with granules in focus to show strongly positive reaction Figs 5, 6, and 7—Early erythroblasts showing a stronger reaction of the nucleus than cytoplasm with the exception of a well defined cytoplasmic reaction zone Figs 8, 9 and 10—Lymphocytes showing a strong reaction in the region of the Golgi element Fig 11—Plasmacyte with characteristic reaction Fig 12—Unidentified cell with strongly positive cytoplasmic reaction zone

Nucleoli (fig 2) did not stain or at least they reacted less intensively than the remainder of the nucleus They were frequently surrounded by a chromatin condensation which was very reminiscent of the nucleolus associated chromatin studied by Swedish authors

In other slides nuclear pattern was somewhat obscured and more uniform than that referred to above, although it did not prevent cell identification This was

especially true for mature neutrophils and erythroblasts, where the block nuclear pattern became indistinct. In a few slides, nuclear pattern was thread-like similar to that observed after acetone fixation. In these slides a slight to moderate cytoplasmic reaction of neutrophils and erythroblasts was observed, but other

general points were coincident with the best preserved smears. Mitotic chromosomes (fig. 14) reacted strongly, in contrast with a negative or slightly reacting cytoplasm.

Part of the erythroblasts, lymphocytes, plasmacytes and megakaryocytes presented a localized cytoplasmic reaction that will be described below.

FIGS 16-24—PHOTOMICROGRAPHS OF HUMAN MARROW SMEARS AFTER ALKALINE PHOSPHATASE REACTION Magnification 1940 diameters excepting figs 16 and 17 which are 1600 diameters Reduction about  $\frac{1}{3}$  off Fig 16—Promyelocyte myelocyte and three segmented neutrophils two of which show a moderately positive cytoplasmic reaction Fig 17—Promyelocyte, metamyelocyte two stab forms and five segmented neutrophils Note cracks in some cells Fig 18—Eosinophilic metamyelocyte with negative reaction of specific granules Fig 19—Immature cells of neutrophilic series strongly positive nuclear reaction Fig 20—Early erythroblasts with nearly negative cytoplasmic reaction Fig 21—Plasmyocyte with strong nuclear and moderately diffuse cytoplasmic reaction Fig 22—Megakaryocyte with strong nuclear and nucleolar reaction and moderately diffuse cytoplasmic one Fig 23—Metaphase plate with poorly preserved chromosomes The extraction appearance of the cytoplasmic rim is

*Granulocytic series* Apart from variations in the staining intensity and number of neutrophilic granules referred to above, the general points were constantly encountered in well preserved smears. Cells of the eosinophilic series gave a conspicuous and constant reaction on specific granules—so much so that nuclear detail was sometimes obscured. It was difficult to recognize basophil leukocytes in our normal material. Cells of the granulocytic series are illustrated in figures 1-4.

*Red cell series* The general nuclear and cytoplasmic reactions were like those mentioned previously. In early erythroblasts localized zones of cytoplasmic reaction were frequently apparent (figs. 5-7). There was generally one of these zones but sometimes as many as three were encountered. These zones, which were frequently juxtanuclear in position and well delimited, were either irregular in shape or presented a number of closely arranged granules or rods, but their reaction was occasionally homogeneous. Mature red blood cells did not give a positive reaction.

*Lymphocytes* The nuclear pattern displayed by the reaction in lymphocytes was similar to the characteristic picture obtained with the usual hematologic stains. There were frequently one or two, and sometimes up to five cytoplasmic zones of reaction. Two general results were noted, in one type, the reacting zone was similar to that of some erythroblasts by being homogeneous and poorly defined, in the other and most frequent type the reaction was granular in nature. Sometimes granules were located on a small zone of reacting ground cytoplasm. The zones were frequently juxtanuclear in position, encircling the nucleus when 3 or more in number (figs. 8-10).

*Plasmacytes* Nuclear pattern of plasmacytes was frequently more homogeneous than after common hematologic stains. The cytoplasm was frequently vacuolated and of indistinct contour, in most instances, on a moderate ground cytoplasmic reaction, there were up to 10 small distinct, strongly reacting granules (fig. 11). In rare instances an entirely negative cytoplasm was found.

*Megakaryocytes* They presented a strong nuclear reaction with the usual pattern. In the cytoplasm of all elements there was a large, finely granulated strongly reacting zone with indistinct boundaries. This cytoplasmic zone was frequently juxtanuclear in position and it occasionally covered the nucleus. The remaining cytoplasm stained very lightly and its limits were not well marked (fig. 13). We did not observe well preserved platelets in the normal marrow material, therefore no reference is made to them.

Some cells that could not be identified with certainty, presented zones of cytoplasmic reaction similar to those of erythroblasts or lymphocytes (fig. 12).

#### *Alkaline Phosphatase*

One hundred and eighty smears were stained, about 50 being fixed in formol vapor. Results obtained were less satisfactory than those of the acid technic. Only about 40 per cent of the stained slides were considered good, with appreciable reaction on elements poor in the enzyme. A correlation was evident in the same material between the intensity of staining and incubation period, but comparably rich marrows presented unexplained differences in reaction intensity. As a rule cytologic preservation was not as good as that obtained by the acid tech-

analogous to that occasionally observed in Leishman stained smears. Fig. 14—Immature cell showing strongly positive nucleolar reaction after Wachstein's method. Note weakly positive nuclear reaction of adjacent forms.

Occasionally, cell fragmentation was encountered. After Wachstein's treatment, nuclear reaction was frequently negative, especially in erythroblasts and neutrophils (fig. 24), but the reaction was predominantly nuclear after formol fixation. Nuclear pattern was more homogeneous and blurred than that obtained with common stains and Feulgen reaction. Frequently especially in the neutrophilic series and erythroblasts, a finely granular pattern over a diffuse and homogeneous nuclear reaction was present. Both in granulocytic and red cell series the intensity of nuclear reaction was somewhat parallel to cell maturation. Cytoplasmic reaction was generally negative, except in part of the neutrophils and stab forms, and in plasmacytes. Nonspecific and specific neutrophilic and eosinophilic granules did not stain. Nucleoli reacted almost constantly (fig. 19). They were quite evident in immature cells but because the intensity of their reaction in promyelocytes was not very different from that of the remainder of the nucleus they were rarely demonstrated in these forms. After Wachstein's treatment and formol saline fixation, nucleolar reaction was very conspicuous and constant against a less intense nuclear stain (fig. 24) particularly in the eosinophilic and red cell series. Mitotic figures were also positive (fig. 23), although chromosome preservation was inferior to that obtained by the acid technic.

*Granulocytic series.* In agreement with Wachstein's report,<sup>1</sup> strongly reacting mature neutrophils and stabs were found in our normal material (figs. 16 and 17). In the majority of instances the nucleus and cytoplasm alike stained strongly so that nuclear details were entirely obscured, in other cells the reaction was only nuclear. No estimation of the number of strongly reacting neutrophils was made. This intense reaction on part of the neutrophils was evident in all slides, even in the poorest or least stained, where the remaining cell elements stained slightly. In the eosinophilic series, reaction was nuclear in location, no staining of the granules was ever observed (fig. 18).

*Red cell series.* Erythroblasts stained strongly in the nuclei, and in the best preserved slides they presented a nearly negative cytoplasm (fig. 20). In other slides, where nuclear pattern was less precise and more homogeneous, a slight to moderate cytoplasmic staining could be observed. Mature red blood cells did not stain.

*Plasmacyte series and lymphocytes.* Plasmacytes presented an homogeneous nuclear reaction (fig. 21) and in addition had a strongly reacting and homogeneous cytoplasm. Lymphocytes presented only nuclear reaction, their identification being generally difficult in view of the uniformity of the nuclear pattern.

*Megakaryocytes.* A strong and rather homogeneous reaction was given by the megakaryocytic nuclei. Frequently 10 or more nucleoli were clearly recognized, especially after Wachstein's treatment and formol saline fixation. The cytoplasm gave a moderate reaction (fig. 22). As platelets were not observed in good preservation, we refrain from commenting on them.

## DISCUSSION

### The Methods

Present status of the alkaline method was well discussed by Lison.<sup>8</sup> This author has confirmed and extended previous observations, supporting the specificity of

the method. Two points among others are significant (1) A negative reaction does not indicate the absence of the enzyme, (2) a slight diffusion of the enzyme can occur, thus hampering the interpretation of images on the cytologic scale. We think that under the conditions in which this work was performed the second possibility has been reduced to a minimum.

The specificity of the acid technic has been recently strongly criticized, at least for nervous tissues (Heinzen,<sup>9</sup> Lassek,<sup>10</sup> Bartelmez and Bensley<sup>11</sup>). Lison<sup>8</sup> emphasizes the necessity of a revision of the conditions of the reaction.

Results from this laboratory<sup>12</sup> tend to prove the specificity of the acid technic, for constant agreement has been obtained between chemical and histochemical data (frozen liver sections), in regard to the action of fixatives, the histologic procedure, the effect of temperature, and the inactivation by known enzyme inhibitors (NaF,  $\text{NH}_4\text{OH}$ ).

From the present work we concluded that formol vapor fixation is the procedure that gives the best cytological preservation for both phosphatase technics without extreme enzyme inactivation. In a cytologic study such as this, we think this is a very important point. For a discussion on the best histochemical fixation procedure we refer to Lison.<sup>13</sup>

As can be seen in the observations, the acid method gave more satisfactory and constant results than the alkaline. In the application of both technics we have confirmed the fact already established by Wachstein<sup>1</sup> for the "alkaline method, namely, a correlation between intensity of staining and cellular richness. The reason for this is unknown to us, but especially for the acid technic, the faint reaction of cells (particularly if poor in the enzyme) in poor materials could be partly overcome by extending the incubation period. It seems interesting to note that Fell and Danielli<sup>14</sup> in their study of alkaline phosphatase distribution in experimental wounds pointed to a somewhat similar relationship: mitotic chromosomes gave a stronger reaction where the intensity of staining of the sections was high and the inverse was true where the rate was low. Although in this case we cannot exclude the possibility of diffusion, as pointed out by Lison,<sup>8</sup> we do not think that this occurs in our case, for we generally studied isolated cells and the intercellular background was not stained.

#### *General Histochemical Data*

We shall adhere to general results on blood and bone marrow cell reaction, the staining of specific granules being considered under a separate heading. No thorough attempt will be made to review all papers in which incidental reaction of leukocytes was noted.

*Acid phosphatase.* Gomori<sup>5</sup> working with smears and sections evinced the negativity of all blood cells of all species studied, although round cell infiltrates around strongly positive areas showed some staining (diffusion?). Although Wislocki and Dempsey<sup>15</sup> stated (p. 254) they have studied bone marrow sections incubated at pH 5.0, they do not specify the results so obtained. In a previous note<sup>2</sup> we described the distribution of acid phosphatase in acetone fixed bone marrow smears. Rheingold and Wislocki<sup>3</sup> summarily reported results

obtained on monkey marrow smears and imprints after 80 per cent alcohol fixation. They noted the predominantly nuclear reaction of all cell series and a brownish granulation in the cytoplasm of myelocytes, in addition to diffuse nuclear and cytoplasmic staining. A variable staining for acid phosphatase of tissue lymphocytes has been noted by various authors (for instance Wolf et al.<sup>16</sup>, Wislocki and Dempsey<sup>15</sup>).

We have confirmed and extended the results summarized in our previous note,<sup>2</sup> but in view of the improvement of the results brought about in the fixation procedure and the extension of the materials, some points are to be modified, namely the positivity of nonspecific granules (see previous footnote) was not confirmed, neutrophilic granules stained, although variably, nuclear pattern, contrary to what we stated for acetone fixed smears, in the present material approximated that obtained by the Feulgen reaction. The progressive tendency to assume this pattern, verified by the use of progressively better fixation procedures led us, perhaps somewhat arbitrarily, to assume that this pattern probably conditions the most reliable figures of enzyme distribution, that was the starting point for our description.

*Alkaline phosphatase* Gomori<sup>4</sup> referred to the positivity of circulating blood granulocytes both in smears and sections. In 1943 the same author<sup>17</sup> noted a negative reaction of human leukocytes as observed in normal lung sections. Bourne<sup>18</sup> stated that nuclei of all marrow cells gave a positive reaction in sections, and that there seemed to be a greater staining in the primitive granulocytes than in the primitive red cells. Fell and Danielli<sup>14</sup> described intense cytoplasmic and nuclear reaction of neutrophils and nuclear reaction in migrating monocytes and lymphocytes in experimental wounds of the rat. Wislocki and Dempsey,<sup>15</sup> using monkey bone marrow sections stated that the reaction was spotty, seemingly involving cells in the neighborhood of blood vessels rather indiscriminately, instead of being visibly localized in any specific cell type.

Wachstein,<sup>1</sup> working on blood and bone marrow smears after treatment by an alcohol-ether-celloidin solution noted nuclear and/or cytoplasmic reaction of part of the neutrophils, the remaining cells being negative. Applied to bone marrow smears the technic was not as satisfactory as to blood smears. Not infrequently uneven staining was observed. Groups of cells showed activity while a similar type of cells, when more isolated in other fields, appeared to be devoid of phosphatase. Occasional nuclear staining of red cell series and late neutrophilic forms were noted. Megakaryocytes were, as a rule, negative.

Rheingold and Wislocki<sup>3</sup> studied alkaline phosphatase distribution in sections and imprints of the rhesus monkey bone marrow, it was present in the granulocytic series, especially in myelocytes, diffusely and variably present in cytoplasm and nuclei. Nucleated red cells did not stain. Cytoplasm of megakaryocytes showed a faint diffuse staining.

We agreed with Wachstein<sup>1</sup> on some correlation between cellular richness and staining intensity, although with frequent exceptions as different cases were compared and on the intense staining of part of the stabs and segmented neutrophils. But in many well preserved films all cellular marrow elements stained, therefore,

with the formol vapor fixation we could extend Wachstein's<sup>1</sup> observations and detail them in the cytologic plane.

We agreed with Rheingold and Wislocki<sup>2</sup> on the positivity of granulocytic and megakaryocytic series but could not confirm the negativity of the red cell series. Probably differences in the fixation procedures used can explain this disagreement.

The apparent discrepancies between results obtained by both phosphatase techniques in smears and sections are probably due to the great inactivation of both enzymes, particularly the acid one by fixation and by histologic procedures.<sup>3, 12, 19, 20</sup>

### *The Reaction of Cell Granules*

The constitution of specific granules is reviewed by Neumann<sup>21</sup> for the early literature. Jones<sup>22</sup> and Rheingold and Wislocki<sup>2</sup> reviewed part of the recent progress in this field. This work tends to prove that neutrophilic granules contain acid phosphatase—apart from the irregularity of the reaction—and do not give the alkaline reaction. The positivity of neutrophilic granules to the acid reaction was only apparent after formol fixations, the reaction being negative after Wachstein's treatment or acetone fixation. Unfixed slides also displayed a positive reaction on neutrophilic granules. Rheingold and Wislocki's<sup>2</sup> brownish granulation in myelocytes possibly represents reaction of specific granules. A positive reaction of neutrophilic granules was also found in frozen sections of human placenta treated by the acid technic (incubation period, 3 hours).

We confirmed our previous work<sup>2</sup> on the positive reaction of eosinophilic granules for acid phosphatase, such reaction was evident after Wachstein's treatment, formol and acetone fixations. These granules were negative for alkaline phosphatase. The positive reaction for acid phosphatase does not agree with previous work by Dempsey and Wislocki<sup>15</sup> and Wislocki et al.<sup>23</sup> on sectioned material. Rheingold and Wislocki<sup>2</sup> do not specify if the brownish granulation of myelocytes represents the reaction of eosinophilic granules. The negative reaction of these granules for alkaline phosphatase agrees with previous reports<sup>1, 3, 15, 23</sup> but does not agree with the report by Dalgaard and Dalgaard<sup>24</sup> on the positive reaction of granules of eosinophils in the intestinal mucosa of the rat. It is possible that differences in the techniques used may explain this discrepancy.

Unpublished results from this laboratory have also shown that rat bone marrow eosinophils, guinea pig eosinophils and pseudoeosinophils and chick eosinophils (with regard to their staining reaction) give the acid reaction on their granules. In chick granules (both round and fusiform) the reaction is confined to a central or eccentric well defined point (fig. 15), this localization closely resembles that of fuchsinophilic granules described within avian eosinophilic ones by Oriá<sup>25</sup> in this laboratory.

The positivity of tissue basophils for alkaline phosphatase was reported by previous authors,<sup>15, 24, 26, 27, 29b</sup> as well as that for the acid technic.<sup>2, 19, 23</sup> Since we could not identify basophils in our normal marrow material, we could not extend this to bone marrow elements.

### *The Positive Reaction of Mitotic Figures*

The positive alkaline phosphatase reaction (mitotic chromosomes) in bone marrow cells agrees with previous work on various materials <sup>14 18 20 21 22</sup>

Acid reaction of mitotic chromosomes has also been already described <sup>20 21</sup> All previous authors worked on sections of tissues fixed in acetone or 80 per cent alcohol

### *Reaction of Nucleoli*

This work confirms that of others on sections of various tissues, as to the positivity of nucleoli for the alkaline phosphatase technic <sup>14 20 21 22 23</sup> The negative reaction of nucleoli for the acid technic does not agree with the findings of Wachstein,<sup>20</sup> Bartelmez and Bensley,<sup>21</sup> Sullivan and Gardner<sup>21</sup> on nervous and hepatic tissues, and others. It is possible that these results were conditioned by the fixation procedure. It is of interest that in bone marrow smears fixed in formal saline occasionally there is a positive nucleolar reaction for acid phosphatase. The point is being investigated further.

### *The Negative Red Blood Cell Reaction for Acid Phosphatase*

This negative red blood cell reaction is striking in view of the known richness of red blood cells in this enzyme <sup>24</sup> It was observed after the various fixation procedures had been used. It may be that the enzyme is in the lyoenzyme form, and is extracted in the fixation procedure, or that the negative reaction is due to the nonpenetration of the ions used in the method. In chick's mature red blood cell acid phosphatase was localized exclusively on the nucleus (fig. 15). This agrees with chemical data of Dounce and Seibel <sup>25</sup>

### *Acid Phosphatase Reaction of Cytoplasmic Zones of Lymphocytes, Plasmacytes, and Erythroblasts*

*Lymphocytes* The reaction, although not constant, strikingly suggests the appearance of the Golgi zone of lymphocytes as described and pictured by Richter <sup>26</sup> Compare, for instance, his figures 31, 33, 34, and 35 with our figures 8, 9, and 10. This would be another example of reaction of the Golgi zone for alkaline and acid phosphatase that has been described<sup>22 27 28 29</sup> in a variety of tissues. In the last paper, Deane<sup>29</sup> stated that the same fact was found in tissue polymorphonuclear leukocytes, but did not give any detail. These authors discussed the possible functional significance of the phosphatase reaction of the Golgi zone of various tissues. Paff et al.,<sup>30</sup> in a cytochemical study of normal and malignant mast cells, described and illustrated positive zones of cytoplasmic acid phosphatase reaction and interpreted them as the Golgi apparatus. In lymphocytes, it is tempting to relate it to the probable globulin synthesis by these cells (see, for instance, White and Dougherty<sup>40</sup>). A study of lymphocytes in malignant and virus processes should be of interest.

*Plasmacytes* The cytoplasmic reaction of plasmacytes, on the other hand, does not fit the description of the Golgi apparatus of plasmacytes by Estable<sup>41</sup> and by Ito,<sup>42</sup> both working on sections. The results we report, therefore, await further

interpretation. It is of interest that plasmacyte cytoplasm gives a strong reaction for both phosphatases as these cells have a cytochemical organization pointing to intense nucleoprotein metabolism and protein synthesis.<sup>43</sup>

*Erythroblasts* There is a striking similarity between some of our figures (for instance, fig. 6) and those of Jones<sup>44</sup> of the so called hyaloplasm of primitive erythroblasts after various staining procedures (see, for instance, his figs. 6, 9 and 12, plate 1). Hyaloplasm was shown by this author to represent negative images of mitochondria and probably of the Golgi element. Our figures do not coincide entirely with Cowdry's<sup>45</sup> (his figs. 10 and 20, for instance) of the Golgi apparatus of erythroblasts of guinea pig marrow. Unpublished work with F. T. Mendes has shown that promegaloblasts and part of the basophilic megaloblasts of megaloblastic anemia marrow present conspicuously reacting cytoplasmic zones similar to those of early erythroblasts.

### *Concluding Remarks*

The essentially qualitative results obtained by means of the phosphatase techniques do not permit us to relate our results with any certainty to the qualitative ones on thymonucleic acid,<sup>46</sup> ribonucleic acid (see White<sup>47</sup>), and to the quantitative data on nucleoproteins and proteins of Thorell.<sup>48</sup> The similarity of the acid phosphatase—and to a certain extent also of the alkaline reaction—nuclear pattern to that obtained after Feulgen's stain is suggestive in this connection.

Relationship of phosphatases to nucleoprotein metabolism was suggested by Bourne,<sup>18</sup> Bodian and Mellors,<sup>49</sup> Dempsey and Wislocki,<sup>50</sup> Moog<sup>51</sup> and others. More recent work by Brachet and Jenner,<sup>52</sup> on the parallel between intensity of alkaline phosphatase staining of nuclei of various tissues and turnover of thymonucleic acid phosphorus, and by Montalenti and De Nicola,<sup>53</sup> on the correspondence between alkaline phosphatase nuclear distribution and Feulgen's reaction of gonads of crustaceans, strongly points to that relationship.

The possibility that phosphatases participate in other metabolic lines has also been pointed out by some of the first mentioned authors. Chemical determination of at least the alkaline phosphatase activity if coupled with cellular content estimation of bone marrow should be of value and could be related to chemical data on nucleoproteins such as that of Davidson et al.<sup>54</sup>

### SUMMARY

1. Three minute fixation in formol vapor at 44°C, followed by 15 minute washing proved to be the most satisfactory fixation procedure for both acid and alkaline phosphatase techniques as applied to bone marrow smears.
2. For both techniques a relation between staining intensity and cellular richness was found.
3. The reaction of normal human bone marrow cells to both phosphatase techniques is described. Both are predominantly nuclear in location. Nuclear pattern approached that observed with common staining methods and Feulgen's reaction. Cytoplasmic reaction was nearly negative. Nonspecific and specific granules do not stain after the alkaline technic. Nonspecific granules are negative for acid

phosphatase, while specific neutrophilic are variable, and eosinophilic, constantly positive Nucleoli are negative after the acid technic, being positive for the alkaline enzyme Mitotic chromosomes are positive for both technics Acid phosphatase reaction in cytoplasmic zones of lymphocytes, erythroblasts, plasma cells and megakaryocytes, is described

## ACKNOWLEDGMENTS

Many points pertaining to this paper were discussed with the late Dr José Oriá to whom we owe invaluable stimulation and guidance We are indebted to Prof W Bnno of Montevideo (Uruguay) for kind advice on the Golgi apparatus of blood cells We are deeply indebted to Professor O P Jones of Buffalo for his painstaking help and advice We thank Dr M A Jamra (Section of Hematology Central Laboratory Hospital das Clinicas da Faculdade de Medicina) and Dr J F Pontes (Section of Clinical Therapeutics Hospital das Clinicas da Faculdade de Medicina) for part of the material used in this study We thank Messrs L. Frankenthal and G Lorenzoni for their aid in the preparation of some of the microphotographs

# PRODUCTION OF CHARCOT-LEYDEN CRYSTALS FROM EOSINOPHILS WITH AEROSOL MA

By COMMANDER W W AYRES, MC, U S NAVY

CHARCOT-LEYDEN crystals were first described in 1853 by Charcot,<sup>1</sup> and again in 1872 by Leyden.<sup>2</sup> They still remain enigmatic structures, and there are many conflicting reports in the literature as to their nature and significance. Their chemical nature is undetermined and there is considerable question as to whether they may be formed from normal blood. Thus, Liebreich<sup>3</sup> stated they may be produced from every normal human blood. Also Neumann<sup>4</sup> was able to produce them in normal blood. On the other hand, Thompson and Paddock<sup>5</sup> in a study of the blood of 100 routine hospital admissions found no Charcot-Leyden crystals. There is also considerable question as to whether all eosinophils are capable of forming crystals and whether they are specific for eosinophils. Schwarz<sup>6</sup> stated that the crystals are not an essential component of the eosinophil, since they could not be produced from the blood of all patients with eosinophilia. Again there are reports of the presence of crystals in the absence of eosinophils. Up to the present time there has been no method by which the crystals could be produced with certainty from eosinophils.

It is known that the crystals usually occur in association with eosinophils and that they are remarkably resistant to certain deleterious influences. Harrison<sup>7</sup> has isolated the crystals in pure form from minced leukemic spleens containing the crystals. The crystals have been described in a diverse number of diseases. In the sputum of asthmatics, in leukemic blood and tissues, in allergic nasal polyps, in the blood and tissues of patients with periarthritis nodosa, in the feces in amebiasis, in the feces in helminthiasis, and in the bone marrow of sickle cell anemia. The crystals appear limited to primates, there is only one questionable case in which they were reported in the blood of a frog.

The purpose of this paper is to present a method by which Charcot-Leyden crystals may be produced rapidly and with certainty from eosinophils by means of Aerosol MA\*, and to show that the crystals may be produced in the blood of a high percentage of normal persons and routine hospital admissions.

## METHOD

Four and one half cc of blood obtained by venipuncture is mixed with 0.5 cc of 3.8 per cent solution of sodium citrate. The blood is centrifuged and the buffy coat is removed by means of a capillary pipet. Two separate drops of this buffy coat are placed on a microslide. One of the drops is covered with a cover slip containing Aerosol MA and the other drop with a plain cover slip. According to Beeler,<sup>8</sup> Aerosol MA is dihexyl sodium sulfosuccinate. It is a homologue of Aerosol AY, Aerosol IB, and Aerosol OT and is a commercially pure white waxlike compound which is somewhat hygroscopic. The solu-

\*American Cyanamid Co.

bility is 34.3 grams per 100 cc. of water at 25 C. It has been used as a wetting agent, emulsifying agent and detergent. Aerosol MA is rubbed over about half of the surface of the cover slip. The waxlike nature of the compound permits it to adhere readily to the surface. The cover slips are rimmed with petrolatum and the preparation is placed in a moist chamber to prevent drying. It is observed every twenty-four hours for seven days and the presence or absence of Charcot-Leyden crystals recorded.

The red cells contained in the buffy coat lyse immediately on application of the cover slip containing Aerosol MA, as do most of the leukocytes. The granules of the eosinophils and the Charcot-Leyden crystals do not lyse. The cells in the control preparations show little or no lysis for several days, and then as a result of bacterial growth. In the Aerosol MA preparations Charcot-Leyden crystals form within a few minutes to several hours while in the control preparations an appreciable number of crystals do not form for seventy-two hours.

Permanent preparations may be made by removing the cover slip with a sliding motion, drying in air, fixing for one minute with absolute methyl alcohol, and staining with the usual hematoxylin-eosin technic. The eosin should be slightly acidified for brilliant coloration.

### RESULTS

The blood of 100 routine hospital admissions was studied by this method and the results are shown graphically in figure 1. In the experimental group, in which the buffy coat was exposed to Aerosol MA, Charcot-Leyden crystals formed in 99 per cent of the cases by the first day. These all remained positive on the second, third and fourth days. On the fifth day one slide became negative for crystals to give a value of 98 per cent. Another slide became negative on the sixth and seventh days to give a final value of these last 2 days of 97 per cent. In the control group, none of the slides were positive the first day, 3 were positive the second day, 12 on the third day, 44 on the fourth day, 64 on the fifth day, and 75 on the sixth and seventh days. The figure 75, however, does not give a true value for the total number of cases that were positive, since on the latter two days as some slides became positive, others became negative. Actually, 80 per cent of the control group showed Charcot-Leyden crystals at one or more times.

In no case in the experimental group were Charcot-Leyden crystals found in the absence of eosinophils. In the control group, most of the cases which failed to show Charcot-Leyden crystals did show eosinophils.

It should be emphasized that the experimental preparations contained crystals in large numbers, directly proportionate to the number of eosinophils, and that the control preparations never showed crystals in the numbers seen in the corresponding experimental preparations.

The 100 hospital admissions were unselected and had a variety of diseases, such as hypertension, diabetes mellitus, Hodgkin's disease, abscess of the prostate, varicose veins, pneumonia, and fractures. Thirty-seven per cent of the patients had a total white count of over 10,000. In no patient was the total white count under 5,000. In 12 per cent of the patients there was an eosinophilia of over 5 per cent, the highest being 12 per cent. In 14 per cent of the cases the diagnosis was not determined. In the remaining 86, only 5 had the diagnosis of a possible allergic disease. There was no case of asthma, allergic rhinitis, or serum sickness.

The blood of 24 normal students was studied with the same technic, the results of which are shown in figure 2. In the Aerosol MA preparation 90 per cent were positive the first day for Charcot-Leyden crystals and remained positive throughout

the seven days of observation. In the control preparations, none of the slides were positive on the first and second days, 87 per cent were positive on the third day,

FIG 1.—CHARCOT LEYDEN CRYSTALS IN AEROSOL AND CONTROL PREPARATIONS IN 100 ROUTINE HOSPITAL ADMISSIONS

FIG 2.—CHARCOT LEYDEN CRYSTALS IN AEROSOL AND CONTROL PREPARATIONS IN 24 NORMAL PERSONS

31 per cent on the fourth day, 46 per cent on the fifth day, 54 per cent on the sixth day, and 58 per cent on the seventh day. All the control and experimental slides remained positive throughout the seven days.

The shape of the Charcot-Leyden crystal is that of a hexagonal pyramid with bases opposed, as shown in figures 3 and 4. Their hexagonal shape in cross section is well illustrated in figure 5. This is a paraffin section of eosinophilic granuloma of bone, stained with Gram-Weigert's stain. Their size is ordinarily described as from 7 to 21 microns in length. In this work some crystals were just visible with the oil immersion lens, while others measured 96 microns in length and 9 microns in width. The crystals stain black with iron-hematoxylin and red with hematoxylin-eosin. In fresh preparations they are colorless or have a light yellow tint.

Many observations were made to determine the origin of Charcot-Leyden crystals. They arise in two ways, intracellularly and extracellularly. Most of the crystals arise within the cell. The crystals elevate, then puncture the cell membrane. More than one crystal may be formed within a cell. It is the usual picture with the

FIG. 3.—DIAGRAM OF CHARCOT-LEYDEN CRYSTAL

Aerosol MA method to see almost every eosinophil with one or more Charcot-Leyden crystals protruding from the cell. Often the crystals lie alongside the cell. Those crystals that arise extracellularly, first appear as minute crystals which gradually increase in size.

It is significant that, with the exception of the eosinophil granules and the Charcot-Leyden crystals, all formed elements of the blood are lysed, indicating that these granules and crystals are remarkably resistant to reduction in surface tension. The nucleus of the eosinophil is dissolved by Aerosol MA, since even after brief exposure to Aerosol MA, the nucleus of the eosinophil appears washed out and does not stain with Wright's stain. In control preparations, even after several days, some chromatin of the nucleus of the eosinophil takes the stain. There is no apparent reduction in eosinophil granules, nor change in their staining reaction, indicating that the crystals do not arise from the granules. It is probable then that the Charcot-Leyden crystals arise from the nucleus of the eosinophil, although this has not been proved.

It was stated by Schwarz<sup>8</sup> that the Charcot-Leyden crystal is not an essential

component of the eosinophil. Thus, Brown<sup>9</sup> studied the blood of a patient with trichiniasis who had 68 per cent eosinophils and was unable to produce Charcot-Leyden crystals. In our work, however, whenever eosinophils were found in blood

FIG 4—CHARCOT LEYDEN CRYSTAL IN WET PREPARATION X900

FIG 5—CROSS SECTION OF CHARCOT LEYDEN CRYSTAL SHOWING HEXAGONAL SHAPE X900

or in tissue, they could be made to produce Charcot-Leyden crystals with Aerosol MA. Conversely, no crystals were found in blood or tissue in which eosinophils were absent. Also the number of crystals formed was directly proportional to the

number of eosinophils present. Preliminary work indicates that the Charcot-Leyden crystal is not only an essential component of the eosinophil, but it is also specific for the eosinophil.

In patients with considerable eosinophilia, the crystals may be demonstrated in whole blood. The technic is the same as described, except a drop of blood obtained from a small wound of the finger is used instead of the buffy coat. In one patient with eosinophilia of 60 per cent, of unknown origin, associated with transient erythematous swellings of the subcutaneous tissues, crystals of large size could be demonstrated in the peripheral blood in a few minutes by use of Aerosol MA.

Another patient with embryonal carcinoma of the testicle metastatic to the lungs was studied. He had a pleural effusion containing about 95 per cent eosinophils.

FIG. 6—CHARCOT-LEYDEN CRYSTALS SHOWING BLUNT ENDS. X900

The centrifugate of this fluid was then almost pure eosinophils. When this centrifugate was mixed with Aerosol MA, very large abnormal crystals with blunt ends were formed, together with normal crystals. The largest of the crystals measured 96 microns in length and 9 microns in width (figure 6). It is believed that the malignancy was not responsible for the formation of the abnormal crystals. The more logical explanation is that the substance which forms Charcot-Leyden crystals was here present in such a large amount and subject to the influence of Aerosol MA that unusually large and abnormal crystals were formed.

A study was made of a patient with discoid lupus erythematosus of the face of thirty years' duration during an acute exacerbation. He showed an eosinophilia of 36 per cent. The buffy coat of the blood of this patient when mixed with Aerosol MA formed crystals within two minutes, the largest of which measured 200 microns in length. This represents about ten times the usual size of Charcot-Leyden crystals. Some of these crystals were remarkable in that they were fused in their

centers. The control preparation showed crystals in two days. On treatment with Bismarsen intramuscularly, the patient rapidly improved, the rash almost entirely disappeared, the eosinophils decreased to 6 per cent and lost their ability to form Charcot-Leyden crystals rapidly and of the abnormally large size. The inference is that some test based on the size and time of appearance of the crystals may be evolved by which the progress of allergic diseases can be determined.

### DISCUSSION

Reports in the older literature repeatedly emphasize that for the production of Charcot-Leyden crystals, the preparations must stand for a considerable period of time. It is also emphasized that large numbers may be found in the bone marrow of cadavers showing autolytic changes. In these cases there is almost always growth of bacteria and the release of ferments by the destruction of cells during autolysis.

It is believed then that the mechanism for the formation of Charcot-Leyden crystals relates to the destruction of the eosinophil by these various lytic agents. In this work, the control preparations did not become positive until the bacterial growth was quite heavy, and the majority of red cells and white cells showed degenerative changes. It is then believed that the mechanism of the action of Aerosol MA is related to its marked lysing effect due to its ability to lower surface tension. The conflicting reports in the literature then become understandable, in those cases in which the eosinophils were subject to lytic influences either by bacterial or enzymatic action, large numbers of crystals were produced, while the reverse happened if they were not subject to such influences. By the use of Aerosol MA these lytic factors may be controlled, with production of crystals from eosinophils in all tissues in which eosinophils were found.

Of particular interest is the work of Turner et al.<sup>10</sup> on the relationship of the eosinophil to the Gordon phenomenon. They showed that the agent producing encephalitis in rabbits was found only in the presence of the eosinophils. They also showed that the test was only positive in those cases of Hodgkin's disease in which eosinophils were found in the tissue. The exact nature of the exciting agent is unknown. Turner and his co-workers suggest that it is related to the Charcot-Leyden crystal. Support for this theory is that for the production of the agent, the tissue must autolyze in the refrigerator for 1 to 2 weeks to obtain a positive test—a factor favoring the production of Charcot-Leyden crystals.

At present this method of producing Charcot-Leyden crystals by means of Aerosol MA has no practical significance. It should simplify, however, the isolation of the crystals, the determination of their chemical structure, and thus lead to a better understanding of the eosinophil and the diseases with which it is associated.

### CONCLUSIONS

1. A method using Aerosol MA is presented by which Charcot-Leyden crystals may be formed from eosinophils with certainty, rapidity, and in quantity.

2. With the Aerosol MA method Charcot-Leyden crystals were demonstrated in 99 percent of the blood of 100 routine hospital admissions, the crystals were demonstrated in 80 per cent of the control group. With the Aerosol MA method

Charcot-Leyden crystals were demonstrated in 90 per cent of normal persons, the control group was positive for crystals in 58 per cent

3 Preliminary work indicates that the Charcot-Leyden crystal is not only an essential component of the eosinophil, but it is specific for the eosinophil

## EOSINOPHILIC LEUKEMIA

REPORT OF A CASE WITH AUTOPSY CONFIRMATION, REVIEW OF THE LITERATURE

By THEODORE S EVANS, M D , AND ROBERT R NESBIT, M D

IT IS FORTUNATE for the orderly and steady progress of medicine that there is, in the profession, a large group of observers slow to accept what is new and unproven, and so it has been true that as each form of leukemia has been described, there has always been a fairly large number of doubting Thomases. This was true when the cleavage between myeloid and lymphoid leukemia was first asserted by Neumann in 1870 and proven by Naegeli and others in 1900. The description by Schilling of a third type of leukemia was greeted by a storm of protest, and the existence of monocytic leukemia is still denied by able and thoughtful observers some thirty-five years after Schilling's original contribution. The existence of basophilic leukemia was first predicated by Joachim in 1906, and more recently studies have appeared by Doan, Groat and others.

Individuals with leukemia showing a marked peripheral eosinophilia have been studied intensively by many workers. In 1912 Stillman described such a case, but many later observers have denied that this was a case of true leukemia. Our own studies indicate that this was probably the first reported case of chronic myeloid leukemia with marked eosinophilic predominance.

We have been impressed in the study of the subject by the following facts:

1. There are comparatively few reports of cases of eosinophilic leukemia, and its occurrence must be quite rare.
2. Many of the reported cases are lacking in essential data as to the maturity of the eosinophils in the peripheral blood, and their descriptions are often inadequate.
3. While many of the case reports include autopsy material, only a small number present evidence regarding the state of the bone marrow during life.
4. In only rare instances have the results of serial bone marrow studies been recorded.

If we accept as a fact that the normal definitive eosinophil is derived from the myeloblast via maturation stages in the bone marrow, then it would seem to be of value to report a case in which studies of both the blood and of the bone marrow showed at first a preponderance of mature eosinophils with later a gradual left shift until finally, myeloblasts replaced a large proportion of the granular cells in both marrow and blood. Hay and Evans, and Thomsen and Plum have reported such instances and have commented upon the value of such information. In our own case of acute eosinophilic leukemia, serial bone marrow examinations and blood films were studied over a period of three months, during which time the gradual change from mature eosinophils through eosinophilic myelocytes to

From the Medical Service of Dr. William Denney and the Pathological Service of the Hospital of St. Raphael, New Haven, Conn.

myeloblasts was evident. While it is impossible to prove that eosinophilic leukemia is a separate and distinct disease entity, paralleling in its life cycle the other well-established types, we believe, however, that the evidence presented adds strongly to previously accumulated data in support of this assumption.

Shapiro in 1919 reported a case of acute eosinophilic leukemia, as did MacDonald and Shaw in 1922, whereas most of the earlier observers referred to their cases as coëxistent eosinophilia and hyperleukocytosis, suggesting that the syndrome may be merely a variant of myeloid leukemia. On the other hand, McGowan and Parker, Stephens, Friedman et al., Thomsen and Plum and others hold that it is a disease entity. At this time there are many proponents of both points of view, and no general agreement has been reached.

### REPORT OF A CASE

A G a 53 year old white female was admitted to the Hospital of St. Raphael\* on June 26, 1946, and died on September 7, 1946.

For approximately five years prior to admission, the patient suffered periodically from itching lumps on the legs. She had been treated with various ointments. These itching subcutaneous lesions would disappear for long periods. In the summer of 1946 they had become fairly widespread and constant and the patient was admitted to the hospital for study. In addition to these itching lumps she complained of recurring attacks of bronchitis and upper respiratory infections which had been noted for many years. The rest of the systemic history was essentially negative. She had lost no strength or weight and slept well except for the pruritis.

Examination revealed an obese, poorly developed woman with rather flabby musculature. The skin was widely and deeply excoriated from scratching so that most of the lesions were almost unrecognizable but a few relatively recent ones were found. The patient stated that they first appeared as lumps beneath the skin which later reached the surface and became red and itchy. Deep-seated masses were found in areas where there was no superficial redness and which did not itch, and other lesions which had reached the surface and had become red and itchy. The masses were rather firm. There was no lymphadenopathy. The moderate fever was assumed to be due to the sepsis from scratching of the skin and consequent infection.

Four days after admission clinical and roentgen ray evidence of broncho-pneumonia was found at both bases. She was treated with penicillin and a favorable response occurred but during the ten weeks in the hospital four similar episodes of fever and lung signs appeared, each of which she survived.

A dermatologist concluded that dermatitis herpetiformis was present. Treatment was ineffective.

A biopsy of the skin lesions gave no evidence of periarthritis nodosa, but mature eosinophilic granulocytes were seen in large numbers, particularly surrounding the blood vessels.

Because of the finding of anemia without any obvious bleeding a hematologic survey was performed early in July. By this time there was some enlargement of the lymph-nodular system and the tip of the spleen could be felt. The peripheral blood showed marked achromia, anis- and poikilocytosis and increased polychromatophilia. Platelets appeared to be present in normal numbers. There was very marked leukocytosis and about 25 per cent of all white cells were adult eosinophils. These were very large, multilobulated and well filled with large granules staining deep red with Wright's stain. Lymphocytes and monocytes appeared to be present in normal numbers proportion and morphology. Sternal puncture showed numbers of active megakaryocytes. There was a marked reduction in the number of nucleated red cells. All stages of myeloid cells were identified from myeloblasts to adult polymorphonuclear cells. The most unusual feature of this marrow was the very large proportion of eosinophils which made up a large part of the total number of white cells.

There was only a slight tendency toward left shift. The eosinophils were very large with polymorphous nuclei. The granules seemed somewhat larger than are usually seen and appeared to be grouped less

\*Service of Dr. William Dennehy

evenly in the cells. The granules also had a tendency to irregular staining with a few cells containing both red and blue staining elements. The average number of granules in each cell was somewhat less than usual. These changes have been described in whole or in part in the cases of Stillman, Shapiro, MacDonald and Shaw, Hay and Evans, and Thomsen and Plum.

Erythropoiesis seemed to have been depressed by the very large concentration of adult eosinophils. The erythro-granulocytic ratio was 1:9.

Tests of the urine, stools, blood nonprotein nitrogen, blood sugar, blood calcium, serology, bleeding, clotting and clot retraction time were normal. The basal metabolic rate was +15 per cent. The erythrocyte sedimentation time was normal. All other causes of eosinophilia appeared to have been eliminated so that the hematologic impression was granulocytic leukemia with marked eosinophilia.

There was a constant eosinophilia during the last eight weeks of life. This varied from time to time but was always beyond normal limits. Serial bone marrow studies showed a steadily increasing tendency toward left shift in the myeloid series. At first many myelocytes, C, were identified in the eosinophilic series. With each succeeding examination of the bone marrow, more B and A eosinophilic myelocytes were seen and finally the bone marrow became strongly blastic in character. The final examination

of the bone marrow performed on the day before death revealed a large percentage of myeloblasts with many early (immature) eosinophils.

The patient's condition slowly but definitely worsened with increasing fever, tachycardia, weakness and anorexia. The spleen and liver increased slowly in size and death ensued on September 7, 1946. The clinical diagnosis of leukemia of the myeloblastic type with marked persistent eosinophilia in eosinophilic leukemia was made.

*Postmortem examination* was performed ten and three fourths hours after death. The body was that of a well-developed, moderately obese, middle-aged female. The external body markings of import were marked pallor of the skin and mucous surfaces, superficial ulcerations of the lips, edges of the tongue and buccal mucosa, and a recently incised focus on the left side of the back which appeared to be healing. No evidence of the skin lesions mentioned in the clinical note was seen.

The peritoneal cavity contained no fluid but showed a mass of dense adhesions around the gallbladder. Pleural and pericardial cavities were free of adhesions. Pericardial fluid was normal.

*Heart* 420 Gm. The viscus was markedly pallid. The arteries were slightly thickened but their lumina were patent. Section of the myocardium showed slight gray streaking. The endocardium and valves showed nothing of gross note.

Sections showed a mild degree of infiltration of the epicardial fat by leukemic cells including blast forms, myelocytes and young lobulated forms. Many of these were of the eosinophilic class. The myocardium showed no infiltration and the cells and fibers were normal. There was no fractionating of fibers and striations were normal. The endocardium appeared normal.

*Lungs* Rt. 710 Gm. Left 605 Gm. The two lungs were grossly similar, presenting dark purple red

markedly subcrepitant bases with meaty texture, and very pallid slightly subcrepitant upper lobes. Section revealed markedly increased blood content in the bases, and frothy blood tinged fluid in the remainder, including the smaller bronchi. No foci of consolidation were demonstrable.

Sections revealed an increasingly prominent leukemic infiltration from above downward. Sections of the upper portions showed moderate crowding of the vessels of the alveoli with cells of the leukemic infiltrate, but more marked was filling of the alveolar spaces with precipitated, pink-staining albuminous material in which was a scattering of "heart failure" cells some containing phagocytosed erythrocyte debris, and a few erythrocytes. Sections of the lower lobes revealed intense plugging of the capillaries so much so that the walls of alveoli appeared to be composed of hyperchromatic cells mostly round cell types, which are identifiable as blast and myelocytic forms. These were seen to be just outside of the alveolar epithelium in markedly distended capillaries. The erythrocyte content of these capillaries was practically nil so great was the plugging with the leukemic cells. In many instances there had been rupture of capillaries and adjacent walls of the alveoli so that the alveolar spaces were completely filled with infiltrating leukemic cells and a moderate number of erythrocytes. Large foci were seen that represented confluent ruptured alveoli with air-bubbles in the mass of blast and myelocytic cells. Other fields showed compression of alveolar spaces by the leukemic cells in distended neighboring alveoli.

TABLE 2.—Bone Marrow Differential Counts

Date	Polys	Bands	Myel C	Myel B	Myel A	Blasts	Total Eos	Young Eos	Lym	Mono	Norm	Erythr
7-7	20	25	45	6	2	2	45	15	2	5	9	3

E. M. ratio approximately 1:9. 45% of the nucleated white cells were eosinophils and most of these were adult cells. A few B and A eosinophilic myelocytes were seen.

8-7	15	17	40	14	6	8	45	22				
-----	----	----	----	----	---	---	----	----	--	--	--	--

45% of the total number of white cells were eosinophils but there was a left shift throughout the myeloid series including the eosinophilic strain.

9-6	12	21	15	13	10	29	46	38				
-----	----	----	----	----	----	----	----	----	--	--	--	--

On this examination there was seen to be a very marked left shift with the presence of 29% myeloblasts. In addition 38% of the eosinophils were myelocytes and there were some cells in which both blue and red staining granules are identified. Many cells were seen in mitosis.

*Spleen.* 1235 Gm. This organ was greatly enlarged and its capsule tense and ironed out but the consistency was of a tensely fluctuant nature rather than hard. When sectioned the cut surface everted and rolled the stretched capsule back. The cut surface was predominantly gray in color and the pulp, greatly increased, was essentially of gray color. To touch this surface was greasy.

Sections revealed sinusoids packed with leukemic cells of the type already described and large foci of acute necrosis some of which could be seen to be splenic follicles. These foci contained neutrophilic polymorphonuclears and macrophages, in a mass of necrotic cells. Some other foci showed replacement fibrosis of these necrotic islands this of varied age some partly hyalinized others with young fibroblasts proliferating in foci still showing some of the acute process. Besides the leukemic cells, there were, in the sinusoids scatterings of macrophages containing engulfed cell fragments, and pigment. The endothelial lining cells were not remarkable except that they were generally flattened by the widely distended sinusoids.

*Pancreas.* 85 Gm. Grossly, the pancreas showed normal surface and section markings, and its duct appeared normal.

Sections showed infiltration essentially peribiliary, and in only rare instances was there any infiltration from the peribiliary connective tissues into the gland itself. The capillaries contained the leukemic cells in large numbers, but they were noticeably absent from the parenchyma of the gland. The islet and alveolar cells appeared normal and retained normal staining reactions.

TABLE 3 — *Reported Cases of Eosinophilic Leukemia*

Author	Age	Duration	Range of W B C.	Range of eosins	Type eosins	Organs affected
<i>Acute Cases</i>

FIG. 1.—Liver section showing the intense and essentially portal infiltration by the leukemic cells the resulting fatty degeneration also pyknotic nuclei more centrally, and the fading into parenchymatous degeneration near the central vein which is seen to contain large numbers of hyperchromatic cells with large nuclei the leukemic cells. Phloxine hematoxylin  $\times 450$ , enlarged from 35 mm film.

FIG. 2.—Kidney section, showing intense infiltration of the interstitial tissues and at right the concentration of the infiltrating cells in the capillary about Bowman's capsule. The appearance of a round cell stroma is typical of all sections. Phloxine hematoxylin stain enlarged from 35 mm using  $\times 450$ .

FIG 3 —Smear of first bone marrow aspiration showing mature polynuclear neutrophils eosinophiles and late myelocytes

FIG 4 —Smear of third bone marrow aspiration showing many young cells and oo mature polynuclears

*Gastro-intestinal tract* No gross abnormalities were noted. There were no foci of hemorrhage and no ulcerations. The lymphoid patches showed some swelling, but no necrosis.

*Liver* 1625 Gm. There was marked enlargement of the liver, which had a rounded edge, and a pale mixed yellowish brown and white color both on its capsular and cut surfaces. The cut surface bulged prominently and felt greasy. Markings were almost obliterated. No gross abnormalities of the biliary system were demonstrable.

Microscopically, there were two notable processes both most marked in the portal zones of the lobules and fading as the central zones were reached. These were an intense leukemic infiltration of the entire portal region, and a likewise intensely marked fatty degeneration of the hepatic cells. This was combined with moderate crowding of the sinusoids with the leukemic cells though the latter was much less prominent than the portal infiltration. The cells of the liver cords were in varied stages of necrosis as well as fatty degeneration and pyknotic nuclei and disintegrating cytoplasm were common. In the midst of the leukemic process, the bile capillaries stood out and appeared remarkably unaltered. No cirrhotic process was seen and there was no bile duct proliferation. The vessels of the portal region all contained an excess of the leukemic cells as did the central veins. The cells nearest the central veins showed some parenchymatous degeneration but were comparatively well preserved.

*Gallbladder* In the ampullary region of the cavity was a partially impacted calculus, 1 cm. in diameter, composed of concentric layers of cholesterol and pigment about a pigment nucleus.

*Adrenals* Rt. 7 Gm. L. 6 Gm. Aside from marked autolysis of the medullae the glands were not grossly remarkable.

Sections showed very mild spotty infiltration in cortical and medullary zones. Aside from this and marked autolysis of the medullary cells, the glands were essentially normal.

*Kidneys* Rt. 400 Gm., L. 425 Gm. These two organs were similar in gross. They were large and pale. The capsules were free and stripped with ease. The external and cut surfaces were pallid and mottled, and the cut surfaces greasy. Markings were largely obliterated, but the cortico-medullary ratio was retained, though both were greatly increased in width.

Sections showed an intense infiltration of the interstitial tissues by leukemic cells. Of especial note was an intensely marked infiltration of the pericapsular region apparently in the capillaries with no similar distention of the capillaries of the glomerular tufts. The glomeruli stood out normally in the round cell background with normal appearing subcapsular spaces surrounding them and normal Bowman's capsules around the whole. The tubules all classes showed prominent parenchymatous degeneration. The interstitial tissues were so completely infiltrated that in many instances normal tissues were invisible or appeared fragmentarily in small foci. The infiltration extended to the pelvis and calices, where it was seen just beneath the epithelium, the latter appearing normal.

*Lymph nodes* All nodes were greatly enlarged, gray white in color and tense but not hard. Their cut surfaces bulged prominently and were gray and greasy to sight and touch.

Sections revealed a process similar to that in the spleen with the exception of necrosis. Sinusoids were crowded with the leukemic cells and the architecture of the nodes was destroyed by its intensity. The follicles were practically absent and the nodes largely replaced by the leukemic infiltrate.

*The bone marrow* was abundant and almost white but sections were not satisfactory, probably because of the long postmortem period before removal.

A clot in the pulmonary artery was used for Wright's staining and demonstrated the leukemic cells amply. The cells were essentially of the eosinophilic classes of myelocytes with numerous blasts present and a moderate number of mature forms in all classes. Of the mature forms most were eosinophils and the remainder were neutrophils in their staining reaction. A few lymphocytes were seen.

The essential findings were leukemic in origin being most marked in the liver, spleen, kidneys, lymph nodes and lungs. Other changes such as those of fatty degeneration of the liver were secondary to the process. Especially notable were the massive infiltrations of the lungs the essentially portal infiltration of the liver, and the interstitial infiltration of the kidneys. The collection of the infiltrating cells in the pericapsular capillaries of the glomeruli was outstandingly prominent.

#### COMMENT

A complete search of some of the more recent literature has been impossible, since many of the foreign journals are not yet available. Only a few cases of eosino-

philic leukemia have been studied by means of both serial bone marrow spreads and postmortem material. The marrow studies in this case showed a progressive development of the leukemic process. In the earlier study, most of the eosinophils were adult cells. Gradually there was replacement of these mature granulocytes by younger forms (early eosinophilic myelocytes) and eventually a shift to blast cells. The early myelocytes contained both red and blue staining granules within the same cell. These have been noted before by MacDonald and Shaw, Hay and Evans in eosinophilic leukemia and by Doan and Reinhart in basophilic leukemia and have been considered to be evidence of left shift. Additional evidence of left shift is seen in the presence of mitotic figures. The increasing number of young marrow cells appeared largely in the eosinophilic strain—from 15 per cent in the first study to 22 per cent and finally to 38 per cent. The same sequence of events was seen to a lesser extent in the peripheral blood where blasts to the number of 20 per cent appeared at one time. The finding of 45 per cent eosinophils in the peripheral blood of which 30 per cent were young eosinophil granule cells was made on one occasion.

The separation of eosinophilic leukemia from many other conditions which result in secondary eosinophilia in the peripheral blood is always difficult. Stewart has reviewed the literature on familial eosinophilia and Paviot and others, that on eosinophilia associated with malignant disease. Henschen has written a comprehensive review of the whole subject. Reports of eosinophilia with recurrent attacks of lung infiltration (Loeffler's syndrome) are becoming increasingly frequent in the literature. Although our patient had several attacks of pneumonia during the period of observation, there were too many clinical facts at variance with this condition, and the autopsy findings were too definitely conclusive of leukemia to place our case in that category. Periarteritis nodosa was also considered in the differential diagnosis of this case, but skin biopsy was negative for this condition, and postmortem examination did not support this diagnosis.

The diagnosis of eosinophilic leukemia may be initially and tentatively advanced on the persistent presence of a large percentage of eosinophils in the circulating blood. If a considerable and increasing number of these cells are eosinophilic myelocytes, reflecting predominance in the bone marrow, the evidence is still further supportive, and if the disease is fatal and there is invasion of all the organs by these abnormal cells as shown at postmortem examination, the diagnosis may be said to have been established. All of these criteria were present in our case, including the observation of the progressive left shift in the eosinophil granule myelocyte to the myeloblast which predominated terminally.

Doan and Reinhart have reported the presence of an acute dysfunction of the bone marrow, resulting in fulminating basophilic leukemia. They have called attention to the fact that immature elements of the different cell strains may be present at the same time in the blood of a given patient. They have also noted the fact that both basophilic and eosinophilic granules were found in the same cell in basophilic granular cell leukemia but that the basophilic granules were present in larger proportion. Our case is similar in that both types of granules were present in individual cells but differs from theirs in that eosinophilic granules were preponderant. A further parallel to their cases is seen in the fact that our case also

showed a left shift to the primitive cells, however, our case progressed to the blastic phase through eosinophilic granule myelocytes, whereas theirs reached the ultimate state of myeloblastosis through basophilic granule myelocytes. Doan and Reinhart conclude that there is an initial benign, perhaps metabolic disturbance in the granulopoietic equilibrium,—in the normal reciprocal relationships which seem to characterize the body cells in health,—to be followed sooner or later, especially in the later decades of life, by a very differently acting, invasive, metastasizing process much more closely related in clinical course and cellular pathology to the malignant hyperplasia and anaplasia which characterize tumor growths arising in other organs.

The total and proportional number of eosinophil granule cells in our case did not reach the extremely large numbers reported by some other observers, but it should be pointed out in this connection that this patient died in the acute stage of the disease. Death in other types of leukemia often occurs with low peripheral blood counts but with all other evidences of leukemia, and it has been assumed that this is so because the disease is fatal before a massive cellular response is seen in the blood.

#### SUMMARY

1 The data in a case of fatal leukemia with predominant eosinophilia in the peripheral blood and bone marrow are presented, we believe that this case was one of eosinophilic leukemia.

2 During the period of observation, these eosinophils showed progressive immaturity as the symptoms became more severe. Eventually this left shift became so marked that a large proportion of the cells were terminally myeloblasts in both the blood and the bone marrow.

3 Autopsy revealed invasion of many of the tissues and organs with these mature and immature eosinophil granulocytes and with myeloblasts.

#### ACKNOWLEDGMENT

Our thanks for helpful criticism are particularly extended to Dr. Charles Doan and to Dr. William Dameshek.

# MEGAKARYOCYTES IN NORMAL AND IN THROMBOCYTOPENIC INDIVIDUALS

## WITH INTRODUCTION OF A NEW SYSTEM OF DIFFERENTIAL COUNT FOR MEGAKARYOCYTES

By VICTORINO DE LA FUENTE, M D

OF THE THREE principal cellular elements of the bone marrow, the megakaryocytes\* have been least investigated. This paper deals with them as found in (1) hematologically normal individuals and in (2) thrombocytopenic patients. It is the first in a series of papers given to the study of the participation of these cells in various pathologic states.

### THE NORMAL MEGAKARYOCYTE AND ITS DEVELOPMENT

#### *Materials*

The subjects of the present project are human—some normal and others abnormal from the hematologic standpoint.

The statement made below on the normal line of development of the megakaryocytes is an integration of all the observations made on the bone marrow specimens of these individuals.

#### *Methods*

The bone marrow specimens were secured in the usual way by sternal puncture. The amount obtained did not exceed 0.5 cubic centimeters. Without using an anticoagulant, the material was spread on slides as in preparing blood films. Seven to ten smears were made. The smears were made thin, slightly thick and thick. The thick ones were used to obtain a general impression of the condition of the bone marrow at the time of the biopsy. For a differential count of the megakaryocytes, those films were examined which showed a great number of these cells without morphologic distortion. It has been observed that these smears could not be used with satisfaction for the differential examination of the smaller bone marrow cells.

Before sternal puncture was made, the total platelet count in the peripheral blood was determined. Either the wet smear method of Dameshek (D) or the dry method of Fono (F) was employed, depending upon convenience. Other hematologic examinations were carried out to determine normality, or for the sake of diagnosis.

The smears were fixed with Wright's solution and stained with Giemsa's.

The number of megakaryocytes per million nucleated cells was not counted for two reasons: (1) Even in a carefully made smear the megakaryocytes, being heavier than other types of cells, tend to gather more at the initial portion. Hence, more megakaryocytes are to be found in this area than in any other portion of the smear. (2) Since the value is relative and since no method so far is accepted as reliable in determining the absolute number of nucleated cells per unit volume of the bone marrow material, the

\*Due to lack of a generic term embracing all types of megakaryocytes, the latter is used in this paper in two senses: in general, to designate the series in contrast with the myeloid and erythroid series; and in particular, to designate the mature type in contrast with the megakaryoblasts and promegakaryocytes. In what sense it is used in a given sentence may be inferred from the context. When the latter is not clear, a modifier is employed.

result does not justify the time and energy consumed in the procedure. A rough calculation made by an experienced examiner would be sufficient for clinical purposes. One can make a fairly reliable judgment of the general condition of the megakaryocytic tissue from the number of smears used to finish a differential count of 100 cells. With the method used in this project, from one to two smears had to be examined to cover 100 cells when the megakaryocytes were not disturbed. In idiopathic thrombocytopenic purpura, only about one third to one half of a smear was enough.

In order to speed up the examination, the low power objective was used to spot and bring the megakaryocytes within the microscopic field. The cells were then examined under the oil immersion objective for structural details. With this procedure, it is possible to go over the same area twice. To avoid this mistake, thin lines perpendicular to the length of the slide were drawn at various intervals. If the smear is examined under the low power objective beforehand, lines can be drawn on areas free from megakaryocytes.

All the photomicrographs were taken under the same magnification using a 6X ocular. Actual magnification cannot be calculated for lack of equipment. The size of each cell may be estimated by comparing it with the lymphocyte and erythrocytes in figure 15. The description of each picture is incorporated in the text.

### *Origin and Normal Development of the Megakaryocytes*

The origin of the megakaryocyte is largely controversial. It has been traced to almost all types of blood cells and data are at hand to support each theory. Nevertheless, proofs to establish one hypothesis are not so conclusive as to exclude the others.

A better evidence is present with regard to the normal line of development followed by these cells as they mature and give rise to platelets. Knowledge of this is important for clinical purposes, particularly in the classification of cells.

The mode of development had been treated extensively in a previous paper.<sup>1</sup> Additional light has been shed by later observations.

The existence of the megakaryoblast is an indisputable fact. With the low power objective it can be easily distinguished in the smear. It is bigger than other blast cells commonly found in the bone marrow (figs. 1-8).

The preferred mode of multiplication is amitosis. This is supported by the constant increase of amitotic forms (fig. 1) when the total megakaryocytes are increased. That such forms belong to the megakaryocytic series is inferred from the presence, in some instances, of platelets in their cytoplasm (fig. 13). Mitosis occurs rarely.

The maturation usually starts in one of the nucleoli. The latter widens and becomes more transparent (figs. 11 and 12). The process continues towards the margin of the nucleus, which subsequently assumes a lobulated figure (fig. 18). When nucleoli near the nuclear margin undergo the same change, the nucleus presents a rugged and eroded edge with granules strewn in the neighborhood (fig. 10). The presence of a round or oval nucleus in the promegakaryocytic phase (fig. 9) would seem to indicate that after transformation of a portion of the nuclear chromatin into granules, the nucleus may assume a round contour. Forms in the mature stage are seen whose nuclei are reduced to small specks, at times darkly staining, embedded in or surrounded by a mass of granules (figs. 19 and 24).

The origin of the cytoplasmic granules from the nucleus has already been mentioned by Downey.<sup>2</sup>

The granules upon dispersal throughout the cytoplasm may be scattered evenly or may congregate into groups with subsequent formation and fragmentation of

FIGS. 1-17—See text

platelets. At times when formation of normal platelets is disturbed and the peripheral blood is thrombocytopenic, the cytoplasm divides into big shreds.

The so-called blue platelets, which are really fragments of a basophilic cytoplasm, are not peculiar to the megakaryocytes alone. Lymphocytes in the blood

may exhibit the phenomenon too (fig. 15). The same is true of the immature eosinophiles and neutrophils in the bone marrow.

I have expressed the opinion before<sup>1</sup> that the polykaryocyte was an indication of aborted amitosis. This appears to be borne out by subsequent observations. A binuclear or multinuclear mature megakaryocyte may be the resulting form of two

FIGS. 18-25 — See text

processes. It may be the subsequent phase of an amitotic megakaryoblast whose cytoplasm fails to divide. It therefore passes through the promegakaryocytic stage (fig. 17a). Or it may be the result of a complete division of the nucleus of a mature form, in the same manner as may be observed sometimes in a segmented neutrophil. In figure 21, the two lobes are connected by a barely visible filament. In figure 22, the thin bridge between one lobe and the rest of the nucleus is very clear. It is not

far-fetched to suppose that after severance, the lobe would assume an oval shape. The appearance of two lobes connected by a thin thread of chromatin does not argue for the fusion theory. In case of fusion, it is likely that the two nuclei would approach each other tangentially.

### *Classification of the Megakaryocytes*

The differential count is an important tool in the hands of the hematologist. A good system of differential counting, one which reflects adequately and reliably the reaction of the cells to pathologic stimuli, is an invaluable aid to diagnosis, prognosis and evaluation of treatment. This is shown in the Schilling hemogram and Price-Jones curve, which basically is a grouping of erythrocytes according to diameter.

Pathologic states usually alter the process of cellular maturation. Thus, in classifying cells for clinical purposes, this fact should be taken into consideration. Similarly, whenever possible the state of functional activity should also be reflected in the differential count.

We have borne these two things in mind in proposing the following classification of the megakaryocytes. The latter are divided into

*Explanation.* The major division (amitotic forms, etc.) gives an insight into the multiplication and maturation of the cells at the time of aspiration. The subdivision of cells into A, B, etc., measures the physiologic activity of the megakaryocytes with respect to the production of platelets and remotely to the cessation of bleeding.

The megakaryoblast (figs 2-8), promegakaryocyte (figs 9-14, 16, 17a, and 18) and megakaryocyte (figs 19-22 and 24-26) need not be described in detail. Their description found in literature, especially in the article of Dameshek and Miller,<sup>3</sup> leaves nothing to be desired and is adhered to in this paper.

The asynchronous megakaryocyte is one whose nucleus belongs to one stage and whose cytoplasm to another. Unlike the granulocytes, the correlation between the nuclear and cytoplasmic development in the megakaryocytes is not so close. Hence, allowance should be made on this account. Yet a distinct type of megakaryocyte may be isolated from the rest, characterized by a nucleus frankly mature and a cytoplasm that is basophilic, without any trace of granularity and without platelets.

formed. In other words, the development between the nucleus and cytoplasm is separated by one phase, that is, *asynchronous*. This type of cell is seen even in normal individuals. Figure 23 illustrates it. The platelet-like bodies at the lower portion of the cytoplasm are artefacts.

The subdivision of the megakaryocytes into A, B, etc, cells is based on the presence of platelets near or at the margin of the cytoplasm. Platelets found near the nucleus and far from the edge of the cytoplasm are not immediately available to the peripheral circulation. Hence, they are not taken into account in the sub-grouping of the cells from the functional standpoint.

A cells do not exhibit platelets in the cytoplasm, or if they do, the platelets are centrally located. Megakaryoblast A and promegakaryocyte A, except in rare instances (fig. 9), offer no difficulty, for these cells have very scanty cytoplasm so that platelets found in them are always near or at the margin. It is in the mature megakaryocyte that the location of the platelets should be scrutinized. Hence, under megakaryocytes A, mature cells without platelets and those whose platelets are far from the cytoplasmic margin are grouped together. (Figures 2-6 are megakaryoblasts A, figures 9-11, 14, 16 and 17a are promegakaryocytes A. In figure 9, arrow points to a lone platelet well inside the cytoplasm. Figure 19 is a megakaryocyte A. The cytoplasm of this cell is granular. The isolated platelet-like bodies are artefacts.)

B cells are those whose cytoplasm contains one to ten marginal or juxta-marginal platelets. Number 10 has been chosen as the limit, because in the acute form or phase of Werlhof's disease, not a single megakaryocyte with more than ten platelets had been found. On the contrary, the B' cells may be as numerous as in the normal. (Figure 7 is a megakaryoblast B, figure 22a is a promegakaryocyte B, figures 17b, 20 and 21 are megakaryocytes B. Each arrow points to a platelet. Other similar bodies are artefacts.)

C cells are those whose cytoplasm contains more than ten marginal or juxta-marginal platelets. (Figure 8 is a megakaryoblast C. This cell is not found normally and is rare even in pathologic cases. Figures 12, 13 and 18 are promegakaryocytes C. Figures 22b, 24 and 25 are megakaryocytes C. Figure 25 illustrates a nucleus in process of gradual dissolution.)

D cells are those whose cytoplasm is wholly converted into platelets (fig. 26). Polykaryocytes (figs. 13, 17a and 17b) are considered frustrated amitotic forms. They are grouped under either the promegakaryocyte or megakaryocyte, depending upon the developmental stage reached, and into A, B or C cells depending upon the number of platelets present.

In introducing a new classification of cells according to maturity, the greatest difficulty met by the proponent lies in the imparting to his readers, who may wish to investigate its value, the different characteristics found in a cell so that the latter may be placed in the group to which it should belong. The problem is succinctly summed up in the question: At what point does the megakaryoblastic phase end and the promegakaryocytic begin?

In this classification, the cell is considered as a whole. The morphology of the nucleus receives the first attention. When for some reason or other the nucleus

does not provide a clear-cut basis for deciding the age of the cell, the cytoplasm becomes the determining factor

Under the amitotic forms, only those with blastic nuclei are included, because when a multinucleated megakaryocyte enters the promegakaryocytic stage, its cytoplasm appears to be no longer capable of division. A cell is classified as amitotic only when the two or more daughter-nuclei are clearly separated by a portion of the cytoplasm (fig. 1)

In the bone marrow there are other cells which seem to be undergoing amitosis. Most of them are syncytial erythroblasts. However, the amitotic forms of the megakaryocytic series are much bigger than the erythroblasts. When in doubt, nevertheless, it is best not to include the cell in the differential count

FIG. 26—See text. A greater magnification than figures 1-25

A megakaryoblast has commonly a nucleus exhibiting nucleoli (figs. 2, 3, 4, 5, 7 and 8). Sometimes the nucleus is in the initial stage of dividing into several daughter-nuclei (figs. 2, 3, 4 and 8). It has been said that the megakaryoblast does not produce platelets. However, figures are observed with distinct nucleoli in the nucleus and platelets in the cytoplasm (figs. 7 and 8). Megakaryoblast B is not uncommonly observed even in normal individuals. Megakaryoblast C is rare and was seen by the writer only on one occasion.

In some instances, a megakaryoblast is encountered without distinct nucleoli (fig. 6). However, the size would not permit its inclusion into the erythroid or myeloid group. Furthermore, its nuclear chromatin materials are disposed in coarser strands than those of the myeloblast. The cell would appear to be what Downey, Palmer and Powell<sup>4</sup> consider a transitional form from the myeloblast to the megakaryoblast by a process of swelling.

The cell has entered the promegakaryocytic phase when the definite structure of the nucleoli is lost, especially when a transparent zone takes the place of one of the nucleoli (figs. 11 and 12). In the meantime, granules appear. A young promega-

karyocyte may also present an eroded nuclear margin (fig 10) with granules replacing the dissolved nuclear substance. The nucleus prior to entrance into the fully matured state may present a hazy appearance.

There are times when the morphology of the nucleus does not help at all in the classification of the cell. The former looks like one massive dark spot. It may either be a promegakaryocyte or a megakaryocyte, depending upon the cytoplasm. A cytoplasm partly basophilic would cause the cell to be included among the promegakaryocytes, a cytoplasm evenly studded with fine lilac granules among the megakaryocytes. Figure 24 illustrates this variety of cell. The nucleus, situated at the lower pole of the cell, could hardly be made out. The other dark spots consist of intensely staining granules massed together. With the use of a 6X ocular the different portions of the cell may be distinguished.

In the subdivision of the cells into A, B, etc. cells, very little difficulty is encountered. When there is doubt as to whether a structure in the cytoplasm is a platelet or not, it is best to refer to the morphology of isolated platelets in the same bone marrow film or in the smear of the same patient's blood.

It should be stated that the proposed classification may possibly suffer from one defect. It is likely that a given megakaryocyte, which had already shed a large number of platelets into the peripheral circulation, may appear as an A cell. In order to establish or rule out the presence of such an error in a given case, the platelets and their disposition should be examined. In normal and in increased production of platelets, the latter are clustered together in big sheets. In decreased production, very few are seen and they are distributed singly.

Table 1 gives the differential counts of the megakaryocytes in 5 hematologically normal individuals. The patients were from the Eye, Ear, Nose and Throat Ward of the Santo Tomas University Charity Hospital, confined for such troubles as strabismus and other local eye disorders which are known not to affect the general system. Their peripheral blood had been examined and all values were within the normal range.

#### THE MEGAKARYOCYTES IN THROMBOCYTOPENIAS

After Wright had demonstrated the derivation of platelets from fragmenting megakaryocytic cytoplasm, it was logically expected that the origin of thrombocytopenia would be tracked down to a disturbance of this bone marrow element. Except for rare cases, a low platelet count is generally associated with a disturbed megakaryocytic picture.

The following cases of thrombocytopenia of varying etiology exemplify the different types of megakaryocytic response to pathologic stimuli.

#### *Materials*

Twenty cases suffering from different diseases in which thrombocytopenia was present are reported. The megakaryocytic reactions (tables 2, 3 and 4) had been so uniform that they could be separated and classified into three types. The cases are therefore grouped accordingly. The important findings in each case are summarized in tables 2a, 3a and 4a.

*Group I* (table 2a) includes only cases of idiopathic thrombocytopenic purpura. No attempt is made to subdivide the disease into acute and chronic. On the basis of

our observation, a patient may manifest at different periods clinical signs of acuteness or chronicity with corresponding variations in the megakaryocytic picture

The condition of the megakaryocytes in this disease has been the subject of much controversy. Dameshek and Miller<sup>2</sup> reviewed the various opinions, since Frank<sup>5</sup> for the first time suspected a causal relationship between thrombocytopenia and disturbance of the megakaryocytes. The majority of investigators incriminate a disordered spleen as the offending organ in the depression of circulating platelets. This view is supported by the increase of thrombocytes after splenectomy.

However, there is a disagreement over the mode of action. One school holds that the spleen produces a substance, still to be identified, which inhibits the production of platelets from the megakaryocytes.<sup>3</sup> The other postulates a phagocytic aggressiveness of the splenic reticulo-endothelial cells, the megakaryocytes all the while remaining intact.<sup>6</sup>

Inhibition of the platelet-producing activity of the megakaryocytes would naturally result in some kind of alteration in the cells. On this account, the quantitative and qualitative changes undergone by them have been the object of intensive research. Deficient platelet-formation and increase of immature cells had long been observed. Limarzi and Schleicher,<sup>7</sup> in addition, described a toxic form, characterized by a pyknotic nucleus and hyaline cytoplasm. More recently, Dameshek and Miller<sup>2</sup> determined the percentage of megakaryocytes active in the formation of platelets and counted only 14.4 per cent of the total number in the acute form and 34 per cent or less in the chronic. They also noted in both forms an increase in the total number of cells and in the percentage of megakaryoblasts and a proportionate decrease of promegakaryocytes.

In our cases (table 2), we have noticed a similar increase in the total number of megakaryocytic cells. Furthermore, the amitotic forms, found only occasionally in the normal, were invariably present. The megakaryoblasts were more than normal, only in the majority of cases. The values of promegakaryocytes and megakaryocytes were within the normal range. This contrasts with the findings of other investigators. We do not consider the presence of cells with pyknotic nuclei and agranular, hyaline cytoplasm as a specific anomaly in idiopathic thrombocytopenic purpura. This cell, which is included in our division of asynchronic megakaryocytes, may also be found in the normal (table 1).

It has been further observed that when the condition of the patient was severe, the megakaryocytes, both mature and immature, containing more than ten platelets in the cytoplasm were characteristically absent. When remission of symptoms took place, a small number of cells with more than ten platelets in the cytoplasm appeared. The subdivision of each developmental stage of the megakaryocytes, from the functional standpoint, into A, B, C and D cells is based on this observation.

Thus, reappearance of C cells may be considered a good prognostic sign. It certainly is a much more reliable index than the platelet count or the bleeding time, especially when whole blood transfusion was already given, before any hematologic analysis could be made.

In summary, the following changes were found in idiopathic thrombocytopenic

purpura (1) an increase in the total number of megakaryocytes, (2) invariable presence of amitotic forms, (3) occasional increase of megakaryoblasts, and, what is most important of all, (4) absence of C cells in the severe, and marked decrease of the same in the milder forms. All this no doubt points to a rapid multiplication of cells and decided inhibition of their platelet-forming activity without interference with the process of maturation.

*Group II* (table 3a) is composed of diseases associated with chronic splenomegaly. Investigation of the megakaryocytes in this condition has not yet been extensively undertaken. Besides Dameshek and Miller,<sup>2</sup> who included cases of secondary splenomegaly for comparison in their study of idiopathic thrombocytopenic purpura, Cartwright *et al.*<sup>8</sup> made a similar research in cases of kala-azar. They found a marked slackening in the fragmentation of platelets from megakaryocytic cytoplasm.

An analysis of our data on the megakaryocytes (table 3) in this group, which includes 4 cases of malaria, 1 of schistosomiasis and another of Banti's syndrome, shows (1) normal number of megakaryocytic cells, (2) presence of amitotic forms, (3) normal or increased megakaryoblasts, (4) a normal percentage of promegakaryocytes and megakaryocytes, and (5) diminished or absent C cells.

The last finding to my mind constitutes a convincing evidence in favor of the restraining influence exerted by the spleen over the megakaryocytic platelet-producing activity. This theory receives additional support from our investigation of other cases of secondary splenic enlargement which are not included in this report, because thrombocytopenia was absent. In them, the C cells were invariably below the normal percentage. The platelet count was maintained at a normal level by a compensatory increase in the total number of cells.

Case 8 of this group was splenectomized and after four days the platelets rose from 173,000 (D) per cu. mm. to 1,090,000 per cu. mm. and the C cells from 1 per cent to 52 per cent. This result tallied with the findings of American investigators after splenectomy in idiopathic thrombocytopenic purpura.

*Group III* (table 4a) comprises various diseases clinically unalike which nevertheless exhibited similar megakaryocytic reactions. Five were infectious in nature, one chronic myelogenous leukemia, one acute myelogenous leukemia and the last aplastic anemia with normocellular bone marrow. The important changes in the megakaryocytes (table 4) were (1) normal or low total number, (2) diminished promegakaryocytes and (3) complete disappearance or low percentage of C cells. In contrast with the first two groups, here there was a definite hastening of maturation.

Few investigators have studied in detail the changes of the megakaryocytes in these diseases. The data gathered prove to be interesting, since they offer a new, additional explanation for the spontaneous hemorrhages occasionally occurring in lesions of this group. In infection or toxemia, purpura is commonly attributed to a toxic injury suffered by the capillary walls,<sup>9</sup> in bacterial endocarditis to the blocking of small vessels by emboli,<sup>10</sup> and in primary blood dyscrasias to a simple reduction of the number of megakaryocytes.<sup>11</sup> While the purpurogenic action of these factors may not be denied, still our observation indicated that another cause may come into play.

## GENERAL CONCLUSIONS

Even in the normal (table 1) it is obvious that there exists only a loose connection between maturation and function of the megakaryocytes. While in the granulocytic and erythroid series, function is discharged only after attainment of maturity, in the megakaryocytes platelet-formation may take place even at the earliest stage of development. However, the more mature the cells are, the greater is the number of platelets produced.

This dissociation of function from maturation is exaggerated in the abnormal marrow. Cases in Groups I and II showed a distinct arrest of function, while the process of maturation remained normal. The process of maturation in cases of Group III was accelerated with associated depression of platelet-production. To complete the series of disturbances actually observed, we may mention that in many cases of iron-deficiency anemia, the megakaryocytes undergo a rapid rate of maturation, without interference with formation and delivery of platelets to the peripheral blood. In our experience we have not yet encountered a single instance wherein maturation was delayed.

From these facts, we conclude that the principles responsible for maturation and for platelet-production are not the same.

Comparing the differential counts of the megakaryocytes as found in normal and thrombocytopenic individuals, the number of platelets in the peripheral blood appears to be maintained at the normal level of 400,000 to 800,000 (D) per cu mm by 34 to 51 per cent of C cells. A diminution of these cells, unless compensated by a very excessive proliferation, as seen in some cases of chronic myelogenous leukemia, is reflected in the peripheral blood by a low platelet count. Disappearance of C cells corresponds to a thrombocytopenia of less than 100,000 (D) per cu mm.

The platelet count bears no relation to the percentage of B cells.

Comparing the data in tables 2, 3 and 4, it would appear that idiopathic thrombocytopenic purpura does not present a specific megakaryocytic picture, except in the acute stage, where the total number of cells is markedly increased and the C cells are totally absent. The conjunction of these two findings is not seen in other conditions.

The association of thrombocytopenia in any disease with disturbance of the megakaryocytes points to the fact that in general the cause of the former acts through the latter. Thrombotic thrombocytopenic purpura<sup>11-12</sup> may be an exception to this rule. However, in the cases reported no detailed examination of the megakaryocytes, as is possible only in direct smears of the bone marrow, has been made. Chronic splenomegalies secondary to various unrelated lesions offer an additional and strong clinical proof in support of Dameshek's concept of hypersplenism. (We are not yet in a position to evaluate the sequestration-and-phagocytosis theory of Doan<sup>13</sup>.)

The spontaneous hemorrhages in infection and toxemia and in certain primary blood dyscrasias pose a question to which the answer is yet to be found. *Is the thrombocytopenia of this nature also mediated through the spleen?* The latter, as is known, is involved in infection and leukemia, though in a different way. However, the prob-

lem becomes more puzzling when a megakaryocytic picture similar to that found in the two former conditions is associated with an atrophic spleen as in Case 20

#### SUMMARY

The megakaryocytes in 5 normal and 20 thrombocytopenic individuals were studied. The stages of development undergone by the cells were delineated and a new classification, according to maturation and function, was made.

Using this classification, the megakaryocytic reactions in the 20 cases of thrombocytopenia were grouped into three distinct types. The first is characterized by a rapid multiplication of cells and a marked inhibition of platelet-formation without change in the process of maturation. The second is similar to the first with this exception that the total number of cells is not increased. The third reaction shows a normal or low total number of cells, with inhibited platelet-formation and accelerated maturation.

From the collected facts, the following conclusions are inferred: (1) The factors of maturation and of platelet-production affecting the megakaryocytes are different. (2) Certain diseases may disturb either of the two processes or both. (3) The number of platelets in the circulating blood is directly related to the percentage of megakaryocytic C cells in general. (4) Lesions affecting the spleen usually check the fragmentation of platelets from the megakaryocytic cytoplasm. (5) Infection and primary blood disorders may cause changes in the megakaryocytes but the explanation for this is still to be investigated.

#### ACKNOWLEDGMENTS

The writer owes a debt of gratitude to the members of the Eye, Ear, Nose and Throat Department of the University of Santo Tomas and to the medical staff of the North General Hospital for the use of some of their patients in this investigation.

## PLATELET THROMBOSIS IN HUMAN HEMOSTASIS

### A HISTOLOGIC STUDY OF SKIN WOUNDS IN NORMAL AND PURPURIC INDIVIDUALS

By HOWARD D. ZUCKER, M.D.

THE IMPORTANCE of blood platelets and platelet thrombosis in the hemostatic mechanism of rats has recently been demonstrated by M. B. Zucker.<sup>1</sup> In view of the frequency of species variation in anatomy and physiology, it became of interest to obtain evidence for or against a comparable role of platelets in spontaneous human hemostasis. The desirability of such a study was confirmed by a search of the medical literature, very few observations on the mechanism of hemostasis in man have been published since 1882 when Hayem<sup>2</sup> and Bizzozero<sup>3</sup> first reported on the form and function of mammalian blood platelets. This void is in striking contrast to the extremely large literature dealing with the hemorrhagic diseases, blood coagulation, and with blood and isolated blood elements. Much circumstantial evidence concerning the mechanism of hemostasis in man is available from these data.

The technical difficulties in microscopic observation of human vessels during the arrest of hemorrhage have not been overcome. Aplitz<sup>4</sup> and M. B. Zucker<sup>1</sup> have studied mesenteric vessels of small mammals at magnifications sufficient to permit identification of the formed blood elements, this method is impracticable in man. Nail-fold capillary studies, such as those of Macfarlane<sup>5</sup> and of Magnus,<sup>6</sup> are of limited value, since the skin thickness and the refractive similarities of unstained platelets and plasma prevent definitive identification of the wound and vessel contents. Histologic study of fresh, human puncture wounds through serial sections was chosen as a method which would permit analysis of some of the factors involved in human hemostasis. Shortly after these experiments were begun, it was discovered that Aplitz<sup>7</sup> had earlier applied serial section methods to bleeding time puncture wounds, obtained at autopsy.

#### METHODS

The skin of the neck or abdomen of anesthetized surgical patients was cleansed with alcohol and punctured by a small Hagedorn needle, each puncture was designed to penetrate 3-4 mm. beneath the surface. Many puncture wounds in control and purpuric patients failed to exhibit macroscopic bleeding and in such instances puncture was usually repeated at a distance. Microscopic hemorrhage was invariably found when such grossly dry puncture wounds were studied. When visible bleeding ensued, the local bleeding time was recorded by absorption of the drops of blood at half minute intervals.<sup>8</sup>

After puncture, the patient was prepared for operation in the usual manner except that scrubbing directly over the wound was avoided. At the time of his initial incision usually fifteen to twenty minutes after the test, the surgeon removed a small ellipse of skin and subcutaneous fat containing the puncture. The biopsy specimen was trimmed to appropriate size with a straight razor, the epithelial surface flattened on blotting paper and the specimen fixed in half strength Zenker formol solution. After three and a

half hours the block was removed thoroughly washed in running water dehydrated, and paraffin-embedded in routine manner. Serial sections, at 7 micra, were cut through the entire block, and mounted in strips of 4 to 7 sections per slide. Invariably a few sections were lost, but not many from any series. Most slides were stained in Mallory's phosphotungstic acid hematoxylin solution which permits differentiation between erythrocytes, fibrin and platelets and platelet products by structural and staining qualities. Occasional slides were stained with hematoxylin and eosin, or with Weigert's elastica.

Blocks of skin from three patients with normal bleeding times were studied. Two were from the necks of hyperthyroid patients and one from the abdomen of a patient with chronic peptic ulcer. All were removed under ethylene-ether anesthesia with scopolamine and morphine premedication. The local bleeding times were 1½ (no macroscopic bleeding), and 1½ minutes respectively. Further controls seemed unnecessary since in all three the essential findings resembled those reported in Aptiz's<sup>7</sup> autopsy controls.

Four blocks of abdominal skin removed from patients undergoing splenectomy for idiopathic thrombocytopenic purpura were studied. Abstracts of the clinical and pathologic data follow, the hematologic data are presented in table 1. Bleeding times of the experimental punctures are given with the histologic descriptions (Results).

### CASE REPORTS

I. S. H. (562354) A 26 month old male infant with negative family history, past history of recurrent eczema, had a history of intermittent red stools and gingival bleeding since birth. He had had two attacks of generalized purpura. Physical examination revealed closed fontanelles, liver one finger below the costal margin, many petechial and larger hemorrhages in the mouth and over the skin. Splenectomy was performed under ethyl chloride-ether anesthesia with atropine morphine premedication. The spleen weighed 48 Gm. (normal 33) microscopically it showed hyperplasia with slight, acute inflammatory changes, and was considered compatible with the diagnosis of thrombocytopenic purpura hemorrhagica. Postoperatively the patient had pyoderma which cleared under penicillin. Seven months after splenectomy he had no signs or symptoms of further purpura.

II. M. L. (566567) A 22 year old housewife gravid 1 para 1 with family history of allergies, had, herself had childhood eczema and frequent rashes, sometimes with pruritus and urticaria. For three years she had had a butterfly rash over the bridge of her nose which, diagnosed as discoid lupus, was treated with short courses of bismuth and one year before admission with three doses of mapharsen following which patient had three days of fever associated with leukopenia. During the year prior to admission the face lesions had become fainter. During that same year there was onset of a progressively severe hemorrhagic diathesis whose manifestations included severe menorrhagia, and showers of skin petechiae. Physical examination B. P. 106/66. Scaling erythematous lesions over nose. Generalized mucosal and skin petechiae and ecchymoses up to 4 cm. in diameter. Splenectomy was performed under ethylene-ether anesthesia with morphine and hyoscine premedication. The spleen weighed 160 Gm. showed no significant histologic changes and was considered compatible with a diagnosis of thrombocytopenic purpura. Postoperatively there was a three week febrile course attributed to a subphrenic hematoma, thereafter, the patient was well. Her husband, a physician reports her free of signs and symptoms of purpura 8 months after operation.

III. A. H. (565035) A 26 year old woman with negative family history and negative past history was admitted because of easy bruising and recurrent gingival bleeding during the preceding year. More recently epistaxes, prolonged menses and finally, tarry stools and smoky urine had been noted. Physical examination B. P. 110/60. Liver at costal margin. Generalized pinhead and larger mucosal and skin hemorrhages and ecchymoses. Splenectomy was performed under ethylene-ether-curare anesthesia with morphine and atropine premedication. The spleen weighed 86 Gm., and microscopically showed conspicuous blood cell formation mainly erythroblasts and megakaryocytes, a feature found occasionally in thrombocytopenic purpura with secondary anemia. For two and one half weeks the postoperative course was febrile, gingival bleeding continued and petechiae appeared over the lower extremities on ambulation. By two months the patient was sign and symptom free and she remained so until her most recent follow-up visit five months postsplenectomy.

IV. S. C. (565567) A 58 year old businessman with negative family history and without previous illness gave a six year history of gingival bleeding. For one year symptoms had been increasing with

easy bruising and one episode of tarry stools and smoky urine. Physical examination B P 176/80. Negative except for small ecchymoses on the right thigh and evidence of recent gingival hemorrhage. Splenectomy was performed under ethylene-ether anesthesia with morphine and atropine premedication. The spleen weighed 150 Gm and showed no significant histologic changes other than a slightly increased number of eosinophile and polymorphonuclear neutrophile leukocytes compatible with a diagnosis of thrombocytopenic purpura. The postoperative course was uneventful.

## RESULTS

*General Observations* In all of the blocks, the anatomy of the cutaneous blood vessels conforms in every essential to the description by Spalteholz.<sup>9</sup> Without his contrast injection technic, and without the physiologic methods of Chambers and Zweifach,<sup>10</sup> distinction between precapillary arterioles, thoroughfare channels, and postcapillary venules is uncertain, since all are of the order of 8 to 14 micra in diameter, and since their muscular components are attenuated. Identification of these small vessels by tracing them through the series to easily identifiable arterial and venous radicals of the next largest order, is both tedious and difficult, since these larger arterioles and venules characteristically run in close association. No attempt has been made to distinguish between the majority of these minute vessels since the sequels of hemorrhage are found to be the same in all.

Unusual valves, briefly mentioned by Spalteholz,<sup>9</sup> are seen in several blocks. These valves lie in the mouths of small tributary venules exactly at their entrance into a large venule of the 4th venous (subcutaneous) network, the anatomy of these valves is clearly established by observation through the series. Only a few tributary venules exhibit such valves, and conventionally placed valves are also seen in the large venules.

In contrast with the findings of Spalteholz, who reports single capillaries, pre- or postcapillary vessels are often seen dividing into two true capillaries near the peak of a papilla. This contrast may be due to local variation determined by choice of different skin areas.

The structure of the experimental wounds is variable, despite attempts to puncture the skin with uniform technic. None of the wound mouths gape widely. Most of the wounds have a characteristic, narrow, V shape, but while some penetrate only half of the skin thickness, others extend into the subcutaneous fat. Most striking is the variation in the number and caliber of the vessels which have been cut. In blocks where few vessels have been cut, sizeable vessels which have escaped puncture can often be traced through the series within a few micra of the wound edge.

No difference can be made out between the endothelium of blood vessels of control and of purpuric patients, or between the endothelium of smaller and larger vessels. In normal and purpuric skins, the endothelium of opened vessels usually exhibits two or three flattened, pyknotic nuclei near the lips of the vascular wound, the remaining endothelial nuclei are normal.

Although segments of true capillaries are recognized with moderate ease throughout the sections, only rare capillaries can be identified that have been opened by the punctures. Presumably recognition of these vessels is hindered by

the traumatic distortion of their endothelium, and, possibly, by collapse and by endothelial agglutination

*Normal Skin* All of the needle puncture wounds in normal skin are filled by masses of well preserved erythrocytes and strands of fibrin. The fibrin appears in strands of varying density, or in the form of fine needles. The heaviest fibrin bands are oriented in the long axis of the wound, roughly perpendicular to the skin surface, less dense strands are seen threaded in all directions between the red cells. The wound margins have an incomplete, thin fibrin cover, where this is lacking the tissue edges are usually bare, but, in places, platelet masses (*viz* infra) form the lining. Occasional white blood cells, single or in groups, are seen in the coagulum. Smaller and larger refractile fragments of the horny layer may be found in the wounds, some in deep or superficial recesses, others lying at the side of the red cell-fibrin clot, none have tamponaded blood vessels in the manner described by Apitz.<sup>7</sup> No inclusions of other epidermal layers are seen in the wound depths, although small, doorlike strips of the entire epidermis, with distorted, pyknotic nuclei, may be seen opening either inwards or outwards at the wound mouths.

The difficulty of identifying opened true capillaries has been described. No capillaries are plugged by platelet masses. Such open capillaries as are identified have fibrin strands sealing their exposed lips, the sealing fibrin strands lie along the wound margin, and do not enter the lumens of the transected vessels.

One or more precapillary arterioles or postcapillary venules have been transected by each puncture. In these normal skins, every such vessel, save two, is sealed by a small or large platelet plug. A number of loose blood platelets are seen in the stumps of some of these transected vessels, giving the illusion of streaming towards the wound. The stumps are sealed, however, by a densely packed platelet mass, 90 per cent of which protrudes from the stump into the needle puncture tract. Occasional well preserved platelets are made out within the masses, but the bulk of the platelets are already involved in the process of fusion (viscous metamorphosis) which is characteristic of these elements in animal experiments<sup>2, 3, etc</sup> and *in vitro*.<sup>2, 11, etc</sup> These coarsely granular masses, which stain blue-gray in phosphotungstic acid-hematoxylin, bear no resemblance to nearby red cells. At the margins of the fused platelet thrombi there is, characteristically, a thin, darkly stained band which resembles fibrin, but which does not have the clear definition of the fibrin in the adjoining clot. Similar condensed bands, never more than one or two, may sometimes be seen within the plug, but discrete fibers or needles of fibrin are never seen. Single, well preserved red or white blood cells occasionally lie within the platelet thrombi. Exceptions to this mechanism of platelet thrombosis are seen in pre- or postcapillary vessels in two different blocks. In one of these a red cell can be seen squeezing out of an unclosed vessel into the puncture tract, in the second instance a similar vessel, well beneath the germinal layer, is tightly covered by a portion of the fibrin lamella lining the wound tract. Fibrin is not seen within the lumens of any of these thrombosed vessels.

In many sections platelet masses can be seen lying within the wound tract without apparent relation to an opened vessel (fig. 1). Invariably these masses

FIG. 1 —PUNCTURE WOUND OF NORMAL SKIN. A fused platelet mass is seen lying in the red cell fibrin coagulum. The vessel from which the mass originates is not seen in this section.

FIG. 2.—55 MICRON ARTERIOLE IN NORMAL SKIN. Extravasated erythrocytes lie in the perivascular space. The vascular defect is filled by a platelet thrombus which is divided by a remaining shred of vessel wall. Within the thrombus many individual platelets can be identified as well as two trapped leukocytes and several erythrocytes.

FIG. 3 —250 MICRON VENULE IN NORMAL SKIN. A large platelet thrombus seals the gaps in the injured vein wall and obstructs some of the vessel lumen. The thrombus exhibits prominent marginal lamination. India Ink discolors the adjacent fat.

can be traced, through the series, to the stump of a severed small vessel. Thus, in three dimensions, one may picture the normal puncture wound as a tubular tract into which a varying number of small vessels open. Each opened end is sealed by a platelet cork, the bulk of which projects into the tube. The remainder of the tube is filled with a red cell-fibrin clot reaching to, but not beyond, the skin surface, infrequent white cells and small, horny-layer foreign bodies are scattered through the clot.

No vessels greater than 250 micra in diameter have been injured by the experimental punctures. In one block of normal skin an arteriole, measuring 55 micra in its smallest diameter, has been perforated. This vessel lies at the surface of the subcutaneous fat, near the margin of the block. Since no continuity can be demonstrated between this injury and the needle wound, it is believed that the arteriolar damage was sustained during the process of excision. The arteriole is surrounded, along most of its course in the block, by a collar of extravasated erythrocytes which infiltrate into the adjacent fat. Through many sections of the series a defect can be traced in the vessel wall, more than one-third of the circumference is involved at the site of maximum damage. The margins of this vascular wound are not entirely smooth, and a remaining shred of wall, at one end of the series, gives the illusion of two adjacent arterial wounds rather than of a single one. The defect in the arterial wall is completely filled by a fresh platelet thrombus, composed, in large areas, of tightly packed blood platelets so well preserved that each may be distinctly made out. In other areas fusion has occurred and only occasional individual platelets can be made out, here the structure resembles the plugs described in the smaller vessels. Occasional red or white blood cells are included in the thrombus which contains no fibrin, but exhibits the marginal band described in the smaller plugs. The platelet thrombus lies almost entirely within the gap in the arterial wall, some knobby excrescences protrude into the adjacent fat, or, without appreciable obstruction, into the arterial lumen (fig. 2).

A 250 micron venule of the 4th network has been opened in a different case. Again the defect is unrelated to the experimental puncture. This was the only experiment in which an attempt was made to mark the region with an intracutaneous india ink dot. The sections show that the tattooing needle penetrated subcutaneously, and destroyed a considerable segment of vein wall. As with the artery, the vein is surrounded by a pool of extravasated blood, and the defect in its thin wall is entirely sealed by a platelet plug. This is a massive thrombus of somewhat looser construction than the others, for the individual platelets are clearly seen with hairlike, stellate processes radiating between them. In some sections more than half of the circumference of the vein wall is missing, and has been replaced by the thrombus, the vascular lumen is two thirds obliterated at some levels (fig. 3). Other, smaller venules show an entirely similar picture on a reduced scale, one exhibits streaming of individual platelets toward the platelet plugged opening.

No unsealed, injured arteries or veins are found in these normal blocks, except at the extreme periphery where microtome and fixation artefacts are too frequent to permit analysis in serial section.

In uninjured larger vessels, in interstices in the subcutaneous fat, and within

some of the wounds one may see masses of finely granular and linear material which usually stains blue with phosphotungstic acid-hematoxylin, but occasionally stains buff. The granules never exceed 0.4 micra in diameter, and the largest lines are not more than 0.4 by 1 micra, although they tend to coalesce. This material is seen in all my blocks (normal and purpura). It corresponds in appearance to the illustration in Fitzgerald's recent paper<sup>1</sup> on acute febrile thrombocytopenic anemia (his fig. 1). In this laboratory identical material has been seen in the portal vein radicles of routine autopsy liver sections in a variety of conditions, particularly in cases with conspicuous hepatic edema. No systematic search of other organs has been made. This material consists, therefore, of particles much smaller than blood platelets, does not resemble the products of platelet fusion as described here and elsewhere, is seen in conditions unassociated with platelet thrombosis, and is presumed to have no physiological bearing on the present data. I believe it to be a granular precipitate of plasma protein.

*Skin in Idiopathic Thrombocytopenic Purpura.* Case I had two punctures one of which failed to bleed macroscopically, the second puncture bled for 15 minutes, until excision. The sections exhibit a penetrating, superficial wound which, running at an angle of 30° to the skin surface, can be followed through much of the series. This extensive wound is filled with uncoagulated blood, and I believe that it represents enlargement of the second experimental puncture consequent to 15 minutes of active bleeding. A few threads of fibrin are scattered among the red cells, but no platelets are found in any section. Various severed or punctured vessels are encountered. One is a capillary from which red cells can be seen escaping into the wound. A number are opened pre- or postcapillary vessels, none of these are sealed, and most contain and are surrounded by red cells. Several are unsealed, transected or punctured venules (fig. 4). Another is a moderate sized arteriole which opens into the wound from below. No large, injured vessels are encountered.

A second, very superficial puncture wound is seen at one end of this block. Although the puncture never bled macroscopically, it is filled with a red cell fibrin coagulum whose denser fibrin strands are oriented perpendicular to the skin surface. No opened vessels of any caliber are identified in the series, and no platelets or platelet masses are present.

*Case II.* This puncture wound bled for three minutes and was removed at fifteen minutes. It is seen to penetrate to the deepest layers of the corium, but not into the fat. The wound contours are entirely similar to the controls, and the tubular tract is filled with a red cell-fibrin clot. In the depths the densest fibrin strands are oriented in the wound axis, perpendicular to the skin surface, but near the wound mouth the dense strands form a transverse dam, paralleling the skin surface (fig. 5). The few vessels found opening into the tract are all sealed by fibrin strands, none are greater than 10 micra in diameter. No blood platelets or platelet masses are seen. There is prominent dilatation of many capillaries and small vessels.

*Case III.* Two punctures were made, each of which bled for five minutes. In an effort to obtain material of greater interest, a third puncture was made with a

FIG 4—MODERATE SIZED VENULE IN THROMBOCYTOPENIC PURPURA. Blood is seen escaping into the perivascular tissues from a small perforation. Platelets and fibrin are absent.

FIG 5—PUNCTURE WOUND IN THROMBOCYTOPENIC PURPURA. No platelet masses are present. Several dense superficial strands of fibrin parallel the skin surface.

FIG 6—SMALL MUSCULAR VESSEL (12 MICRA) IN PURPURA. (a) Two vessels approach the wound edge which is coated by thin fibrin strands and enmeshed red cells. The opening between the vessels is an artefact. (b) The lower vessel is open (→) its lips are sealed by the overlying fibrin-red cell clot. The artefact is still seen.

large, cutting edged, surgical needle, this wound bled freely for ten minutes, until the entire block was removed

Both of the smaller wounds are filled with fibrin- red cell clots. One, near the edge of the block, has been so distorted by fixation and cutting that it cannot be followed in series. The other is similar in contents, and in the size and appearance of its cut vessels, to the tract of Case II. Unlike Case II the denser fibrin strands in this puncture are oriented perpendicular to the skin surface.

The third wound is U shaped, and about two and one-half times greater in diameter than any of the other wounds studied. It penetrates to the base of the corium. The superficial portions of the wound are empty, perhaps due to falling out of their contents. At the wound margins there is a thin fibrin network with enmeshed red blood cells. The deeper portions of the wound contain a red cell fibrin coagulum in which the uppermost, dense fibrin strands parallel the skin surface. Some opened pre- and postcapillary vessels are encountered at the wound edges, most of these are sealed by fibrin (fig. 6), but some lack seals, as do several capillaries. No larger vessels have been cut. No platelets are seen. Small, finely granular masses suggesting plasma precipitate are present.

*Case IV* Two punctures were made, both of which oozed briefly, the local bleeding times were less than  $\frac{1}{2}$  minute. The block was excised at 20 minutes. Both wounds have the characteristic, narrow V shape, and are filled with fibrin red cell coagula. One penetrates to the deepest corium, ending among some sweat glands, the other penetrates only half of the skin thickness. The denser fibrin strands in both wounds are oriented in the wound axis, perpendicular to the skin surface. A few cut pre- and postcapillary vessels are identified in each wound, very few in the smaller. These vessels, as well as the rare capillaries identified at the wound edges, are sealed by fibrin. No platelets or platelet masses are seen.

### DISCUSSION

*Platelet Agglutination* Intravascular thrombosis, rather than hemostasis, was the subject of Bizzozero's<sup>3</sup> experiments. His investigations, confirmed and elaborated by others,<sup>12-18</sup> have clearly established that mammalian blood platelets rapidly agglutinate at the site of vascular injury. Here they form intravascular platelet thrombi, with the inclusion of occasional red or white blood cells. The massed platelets quickly undergo the same viscous metamorphosis that is seen *in vitro*,<sup>11</sup> and they subsequently become surrounded by secondary clot composed principally of red cells and fibrin. Welch<sup>16</sup> and, particularly, Aschoff<sup>18</sup> have offered much evidence for the identity of experimental thrombi with those encountered in human pathology.

Hemostasis effected by platelet agglutination was first demonstrated by Hayem<sup>2</sup> in an experimental wound of a dog's jugular vein. Lubnitzky,<sup>19</sup> in 1885, reported hemostatic platelet thrombosis in similar wounds of rabbits' cranial arteries. After a lapse of forty years, this early work was confirmed by Apitz<sup>4</sup> and M. B. Zucker,<sup>1</sup> and extended by them in studies involving experimental interference with the hemostatic mechanism, such as the use of heparin, dicumarol, or antiplatelet serum. The present observations confirm Apitz's demonstration that blood platelets also

agglutinate in the defects of cut skin vessels in man. Such platelet thrombi have been seen in vessels ranging from 8 to 250 micra in diameter.

The rate of platelet agglutination in vascular wounds was first studied by Lubnitzky.<sup>19</sup> Her histologic studies show that, in rabbits, an incomplete thrombus fills the arterial gap within fifteen seconds, but that open pathways remaining in the platelet plug are not closed until the end of the first minute. The modern workers<sup>1-4</sup> have watched the formation of platelet thrombi in vascular wounds of small animals, these thrombi, which appear within ten to thirty seconds, become hemostatically effective within four minutes, despite gentle irrigation. My observations indicate that the rate of platelet agglutination in man approximates that seen in other mammals. Thus, viscous metamorphosis seen in blocks removed as early as ten minutes after experimental puncture, indicates that the platelet thrombi have been present for some time. In one instance, an arteriolar wound, thought to have been incurred during the removal of the block, is plugged by a mass of morphologically distinct, unfused platelets, presumably this plug formed in thirty seconds or less.

The normal adhesiveness and cohesiveness of platelet agglutinates has not been quantitatively studied. Lubnitzky<sup>19</sup> showed that unsupported platelets can not resist the blood pressure of large arteries, since platelet thrombosis could be produced in rabbit arteries only if moderate proximal pressure were applied. The present experiments show that in man, even without fibrin backing, a platelet thrombus can resist the effective blood pressure in an arteriole of 55 micra.

The structure of platelet thrombi varies somewhat, according to the nature of the vessel thrombosed. In larger arterioles the platelet masses lie chiefly within the mural defect, but exhibit small intraluminal projections, larger projections may be prevented by the breaking off of tiny emboli, a phenomenon described in experimental animals.<sup>1-4</sup> The platelet thrombi in some venules exhibit large intraluminal projections, probably because fragmentation is less frequent with lower blood pressure. In smaller vessels the plugs are more like mushrooms, with a small stalk lying in the vascular defect, and a larger, extravascular projection. Neither Apitz<sup>7</sup> nor I have seen platelet thrombi in true capillaries.

The factors underlying the deposition and agglutination of platelets are not clarified by my data. The exhibition, at the lips of each severed vessel in the sections, of one or two distorted endothelial nuclei, is no reason to assume a causal relationship with the arrest of platelets at these sites. And, although this endothelial alteration is present in every vessel, no platelets have accumulated at the mouths of opened capillaries, and none have accumulated in the stumps of the cut vessels in cases of thrombocytopenic purpura. The present histologic studies permit no interpretation of the possible hydrodynamic factors<sup>20</sup> involved in platelet agglutination, nor of the chemical or physical factors which render blood platelets agglutinable.<sup>21</sup>

*Fibrin Deposition.* In man, as in experimental animals,<sup>4</sup> there is no evidence that fibrin plays a significant role in platelet thrombus formation. The plugs described by Apitz<sup>7</sup> and by myself contain occasional dense, linear strands, and are usually outlined by thin, perimetric bands, we both consider this material to be

fibrin, but do not believe that it is essential in the structure of platelet thrombi. It is possible that minute quantities of fibrin, not identifiable by routine histologic methods, are formed at the platelet interfaces during thrombosis.

The present observations support those of Schimmelbusch,<sup>11</sup> who first opposed the theory<sup>3</sup> that platelets are the anatomic nidus from which fibrin strands arise. Virtually no fibrin is seen in the pools of extravasated blood which are found surrounding large subcutaneous arterioles and venules exhibiting platelet thrombi. Conversely, abundant fibrin is seen in the platelet free puncture wounds of purpuric patients. Except for the thin perimetric lamellae, the orientation of fibrin within the normal tracts seems unrelated to distribution of the platelet thrombi.

*Hemostasis.* Any tenable theory of normal, spontaneous, human hemostasis must account for the arrest of bleeding within a stated time interval (one to three minutes for small skin wounds<sup>22</sup>), and must account for the prolonged absence of renewed bleeding. Doubtless many factors are operative in the hemostatic mechanism, as is clearly brought out in Tocantins' recent review.<sup>23</sup> Whatever the contributory factors may be, bleeding stops when no more red cells escape from opened vessels, and renewed bleeding can only be prevented by the permanent sealing of opened or severed vessels. An essential problem in hemostasis is, therefore, the nature of the hemostatic vascular seal.

Fibrin formation, i. e., coagulation of the blood, has often been suggested as the mechanism whereby opened vessels are sealed. Hayem<sup>2</sup> raised the objection that fresh blood is continually passing between the lips of vascular wounds, and that such blood will not clot, *in vitro*, within many minutes. His objection seems valid today. In the laboratory, even with excess thromboplastin, human blood does not clot in less than eleven seconds<sup>4</sup>, therefore, even if fibrin be a sufficient seal, a given drop of blood must be delayed for eleven seconds at the lip of the severed vessel if hemostasis is to occur.

Macfarlane,<sup>5</sup> in his stimulating and widely quoted review, has suggested that vascular contraction may account for hemostasis by providing sufficient time for coagulation of extravasated blood. As a corollary it is postulated that fibrin is an adequate hemostatic agent. Common surgical experience contravenes the assumption that red clot is likely to act as an adequate seal for larger vessels. Unligated vessels, in the tonsillar fossa for instance, frequently recommence bleeding despite the presence of abundant red clot. Although Tannenberg and Herrman<sup>24</sup> offered experimental evidence that contraction of small vessels may prevent blood loss, their experiments do not establish that such vasoconstriction is followed by the permanent arrest of hemorrhage. It is possible that in smaller muscular vessels, under some circumstances (*viz. infra*), fibrin may be an adequate seal. Chambers and Zweifach,<sup>10</sup> and the Clarks,<sup>6</sup> have presented evidence that contraction of true capillaries does not take place. Consequently, in the absence of definitive visualization or of histologic confirmation, it is difficult to accept hemostasis by nail-fold capillary contraction, as reported by Macfarlane<sup>5</sup> and by Magnus.<sup>8</sup>

Hayem<sup>2</sup> stated that blood platelets are the essential factor in normal hemostasis, and that other elements are merely accessory and secondary. His theory conforms to modern evidence. In man, Apitz<sup>7</sup> and I have shown that platelet thrombi

normally form in most cut skin vessels larger than capillaries. The present experiments also show that human platelet thrombi can form within the expected time span, and that such thrombi are pressure resistant. The importance of platelets in the normal mechanism preceding clotting is further indicated both by the failure of fibrin formation in briskly bleeding thrombocytopenics who had normal clotting and prothrombin times, and by the delay of fibrin formation in other thrombocytopenics.

One might then picture platelet thrombi as coffer dams which, aided by local vasoconstrictor mechanisms, stop or slow the blood flow to the point where extravasated blood within the wound is given sufficient time to clot. Not all small vessels need have such a plug, for, once the flow has been considerably slowed coagulation will occur, and will seal any small vessels which have not yet accumulated sufficient platelets, rare fibrin-sealed small vessels have actually been seen in my normal blocks, none larger than 12 micra. The formation of fibrin within the wound tract, and its later retraction, represent the construction of a permanent, concrete dam which anchors and reinforces the older platelet thrombus coffers. Once the fibrin has buttressed the platelet thrombi, resumption of normal pressure relationships, as the vasoconstriction relaxes, is less likely to cause renewed bleeding. In contrast, coagulation alone, secondary to tight vasospasm or to obliteration of a vessel lumen by pressure, may fail to maintain hemostasis once the blood pressure is restored, for, without blood flow, thrombi can not have formed.

In capillary hemostasis the platelets may play no role. Neither Apitz<sup>7</sup> nor I have seen platelet plugs in human capillaries. Presumably the chief hemostatic factor in these vessels is the small difference between intracapillary and tissue pressures, this small pressure difference, and reflex contraction at the capillary mouths,<sup>10</sup> result in an ooze of blood from the opened capillaries which is sufficiently slow to permit coagulation within the wound. Evidence for this hypothesis is seen in the normal bleeding times of the puncture wounds of some thrombocytopenics, these wounds contain fibrin-red cell coagula sealing the capillaries, and also the few precapillaries which were cut. Apitz<sup>4</sup> has repeatedly seen immediate, permanent hemostasis in transected animal capillaries, due to endothelial agglutination, presumably this mechanism also occurs in man, and may account for the scant number of opened capillaries visualized.

The architecture of the fibrin meshwork within wounds has not been described in the literature. Consequently, in view of the small series reported here, the fibrin structure can not be stressed. The alignment of the denser fibrin strands in normal wounds may be in the direction of blood flow, for they are aligned in the long axis of the wounds. In contrast, the superficial fibrin layers, in two thrombocytopenics, bridge the wounds parallel to the skin surface, this configuration may be a concomitant of pathologic hemostasis.

The present results, and those of Apitz,<sup>7</sup> confirm the widespread, but previously unsupported, belief that there is great similarity between the human hemostatic mechanism and that of other mammals. The close parallel to the experimental observations of Apitz<sup>4</sup> and M. B. Zucker<sup>1</sup> suggests that associated physiologic

mechanisms, demonstrated in the laboratory but inaccessible to histologic study, also come into play in human hemostasis

**Bleeding Time** The clinical usefulness of the bleeding time is well established<sup>22</sup> A prolonged bleeding time is of pathologic and diagnostic significance, Quick<sup>24</sup> states that it is seen in the thrombocytopenic purpuras and in pseudohemophilia (thrombasthenia) The bleeding time may be normal in toxic purpuras, hypoprotrombinemia, hemophilia, and afibrinogenemia or hypofibrinogenemia

Apitz's studies of bleeding time tracts obtained at postmortem, and the present study of human puncture wounds\* obtained at biopsy give, for the first time, an accurate anatomical picture of such tracts The variability of depth of puncture, and the extreme variation in the size and number of vessels severed or punctured is an outstanding feature As commonly performed, some bleeding time punctures test only capillary bleeding time, while others test the entire mechanism of hemostasis These observations account for the common observation that repeated punctures are needed when hemorrhagic disease is suspected<sup>2</sup>, they probably explain the tendency for bleeding in thrombocytopenic purpura to vary in duration at different skin sites<sup>5</sup> Thus, in four blocks from thrombocytopenic patients, the bleeding time was normal when only capillaries were cut, but was prolonged when larger vessels were cut Clinically every effort should be made to produce deep, sufficiently wide cuts with a sharp blade, probably the size of the first few blots of blood, as suggested by Duke,<sup>8</sup> is the best index of an adequate bleeding time puncture

The prolonged bleeding time of idiopathic thrombocytopenic purpura is accompanied by the absence of platelet thrombi in the severed muscular vessels This absence of platelet plugs confirms Apitz's observations,<sup>7</sup> and is in agreement with the results obtained by Muller,<sup>27</sup> Apitz<sup>28</sup> and M. B. Zucker<sup>1</sup> in experimental thrombocytopenia Thus, loss of the primary hemostatic mechanism of platelet thrombosis, due to quantitative and, possibly, to qualitative platelet deficiency, seems to account for the abnormal bleeding of thrombocytopenic purpura Implication of other factors seems unnecessary If syneresis is of clinical significance, the mechanism substituted in thrombocytopenic purpura, namely coagulation, is also impaired

One might speculate that the prolonged bleeding in pseudohemophilia results from failure of platelet thrombosis on a qualitative basis, and that the notorious tendency towards renewed hemorrhage in hemophilia<sup>24</sup> is based on the lack of a strong fibrin backing for otherwise adequate platelet plugs

#### SUMMARY AND CONCLUSIONS

The histologic appearance of human skin puncture wounds obtained at biopsy, after measurement of the local bleeding times, has been studied in serial section in 3 patients with normal hemostasis and in 4 patients with idiopathic thrombocytopenic purpura It is found that agglutinated platelets arrest hemorrhage in normal skin by rapidly sealing the mouths of all cut vessels larger than capillaries Such

\* Unlike clinical bleeding times these punctures are of the skin of the neck and abdomen

platelet thrombi can resist the effective blood pressure in a cut arteriole of 55 micra. The puncture tract is normally filled with red cell-fibrin clot into which the platelet thrombi protrude. The red clot seals the mouth of the few opened capillaries which can be identified. Other capillaries may be sealed by endothelial agglutination. Fibrin does not enter or form within the injured vessels.

Platelet thrombosis does not occur in idiopathic thrombocytopenic purpura. When larger arterioles and venules are cut the bleeding time is greatly prolonged and fibrin fails to form within the wound because of the speed of blood flow. When smaller vessels are cut in purpura the bleeding time is moderately prolonged, but the cut vessels are eventually sealed by fibrin alone. In thrombocytopenic purpura the bleeding time is normal if only capillaries are cut, since these are normally sealed by fibrin.

The similarity of the histologic appearance of human puncture wounds to that described after experimental vascular injury in other mammals, suggests considerable similarity in mammalian hemostatic mechanisms.

Clinical bleeding time tests vary greatly in depth of puncture and in the caliber and number of the vessels cut. Sufficient volume of hemorrhage during the first minute is thought to be the best guide to an adequate test of the entire hemostatic mechanism.

# THE EFFECT OF THE PARENTERAL INJECTION OF EPINEPHRIN ON LEUKOCYTE COUNTS IN NORMAL SUBJECTS AND IN PATIENTS WITH ADDISON'S DISEASE

B<sub>3</sub> JACQUES L. GABRILOVE, M D, MARIO VOLTERRA, M D, MILDRED D. JACOBS, A B,  
AND LOUIS J. SOFFER, M D

IT HAS been known for many years that the parenteral administration of epinephrin induces marked temporary changes in the white blood cell picture. The mechanism responsible for these changes is still obscure. Interest in this phenomenon, however, has recently been revived since Dougherty and White<sup>1</sup> have demonstrated that the administration of adrenotrophic hormone of the anterior hypophysis or whole adrenal cortical extract results in the destruction of lymphoid tissue with the production of a lymphocytopenia. Long and his group<sup>2</sup> have shown that the injection of epinephrin into experimental animals causes stimulation of the anterior hypophysis with increased secretion of adrenotrophic factor, which in turn stimulates the adrenal cortex. In view of this observation, it was thought desirable to study the effect of epinephrin on the leukocyte count in normal subjects and in patients with Addison's disease, the latter being the closest clinical analogue of the bilaterally adrenalectomized animal.

The lymphocytopenia resulting from adrenal cortical secretion is presumed to be part of the reaction to stress involved in the adaptation syndrome.<sup>3</sup> Pincus et al.<sup>4-5</sup> have used this phenomenon to study reactions to stress in the human as a measure of adrenal cortical secretion.

Conversely, it has long been known, as recently emphasized by De la Balze and co-workers,<sup>6</sup> that patients with Addison's disease have a lymphocytosis associated with a reduction in the total white blood cell count, as well as a decrease in the number of neutrophils.

Previously published studies with epinephrin have almost invariably been short period experiments, usually for less than two hours, since the problem being investigated dealt, for the most part, with the role of the spleen in the ensuing leukocytosis. The administration of epinephrin results initially in a leukocytosis, associated with a sharp increase in the absolute and relative number of lymphocytes. These changes disappear within an hour and are followed by a neutropenia. More recent studies on the effects of epinephrin on the lymphocyte count in normal and adrenalectomized dogs have shown that the former develop a lymphocytopenia which is not observed to occur in the totally adrenalectomized animals.<sup>7</sup>

## METHODS

Ten normal subjects and 11 patients with Addison's disease were studied. Seventy-five hundredths cc of a 1 to 1,000 aqueous epinephrin solution (0.75 milligrams) was administered subcutaneously. Blood for total white blood cell counts and differential studies was obtained from the finger before the administration of epinephrin as well as at fifteen minutes, one hour, two hours, three hours, four hours.

From The Medical Services of The Mount Sinai Hospital, New York.

and five hours following the injection. Smears were stained with Wright's stain and one hundred cells were counted. All tests were performed at approximately the same time of day, from 8 to 9 A.M. to 1 to 2 P.M. Because of the fear of hypoglycemia in the patients with Addison's disease, all subjects were allowed to eat prior to the test and at luncheon time (about 12 noon). All patients experienced palpitation, apprehension, tachycardia and nervousness as the result of the administration of epinephrine.

The diagnosis of Addison's disease had been established in each instance on the basis of adequate clinical and laboratory evidence. All the patients presented the classic clinical picture, and each had been in acute adrenal insufficiency, either occurring spontaneously or induced by salt deprivation on at least one occasion. The characteristic blood electrolyte pattern demonstrating a low serum sodium and chloride and elevation of serum potassium was manifested by every patient of the group selected for study. The members of the group were treated with desoxycorticosterone acetate. None received whole adrenal cortical extract.

FIG. 1—The total white count following the subcutaneous administration of 0.75 cc. of 1/1000 epinephrine. Broken lines denote normal subjects. Continuous lines denote patients with Addison's disease.

### RESULTS

In both normal subjects and in patients with Addison's disease, the total white blood cell count (fig. 1) exhibits a biphasic character with a high early peak and a low late peak. The peaks occur at fifteen minutes to one hour and at three to four hours. The minimum count is noted at two to three hours. In the normal subjects, as opposed to the patients with adrenal hypofunction, the total white blood cell count is initially higher, and maintains a higher level throughout the test. In addition, in normals, the second peak is much higher than it is in patients with Addison's disease.

In both normal subjects and patients with Addison's disease, the absolute neutrophil count exhibits a biphasic curve. The early peak occurs in fifteen minutes to one hour and is low. The minimum count is noted in one to two hours. The second

FIG. 2.—The absolute neutrophil count following the subcutaneous administration of 0.75 cc. of  $1/1000$  epinephrine. Broken lines denote normal subjects. Continuous lines denote patients with Addison's disease.

FIG. 3.—The absolute lymphocyte count following the subcutaneous administration of 0.75 cc. of  $1/1000$  epinephrine. Broken lines denote normal subjects. Continuous lines denote patients with Addison's disease.

FIG 4—The percentage of the original absolute lymphocyte count following the subcutaneous administration of 0.75 cc of 1/1000 epinephrine. Broken lines denote normal subjects. Continuous lines denote patients with Addison's disease.

FIG 5—The percentage of lymphocytes in the differential leukocyte count following the subcutaneous administration of 0.75 cc of 1/1000 epinephrine. Broken lines denote normal subjects. Continuous lines denote patients with Addison's disease.

peak is more pronounced than the primary rise, and the second peak in normals is far greater than that noted in patients with adrenal insufficiency. In general, the absolute lymphocyte count in patients with Addison's disease is initially higher than in normals, and maintains this higher level throughout the test. The overlap is so great that no more pronounced lymphocytopenia in normals as contrasted to patients with Addison's disease can be demonstrated as a means of differentiation between the groups (figs. 2 and 3).

When the percentage of the absolute lymphocyte count at any time compared to the original absolute lymphocyte count is plotted against time, a diphasic curve is noted. Here, too, no definite evidence of more marked lymphocytopenia in the normal as opposed to the patient with Addison's disease is noted (fig. 4).

Although we do not feel that the differential count per se in this test is of significance, we have plotted it merely to illustrate how the relative composition of the blood varies. The lymphocyte percentage in the patient with Addison's disease is initially higher than in the normal, and this higher percentage is maintained throughout the test. In both the normals and the patients with Addison's disease, the percentage of lymphocytes rises early and falls late (fig. 5).

With our technic, employing Wright's stain for differential study, no difference in eosinophilia is noted between the two groups. There is a slight late decrease in eosinophilia following the administration of epinephrin.

### DISCUSSION

On the basis of the results obtained, no clear cut separation can be made in the reaction to epinephrin of the patients with Addison's disease from that of the normal individuals.

Several possibilities exist to explain why the expected altered reaction in the patients with Addison's disease as compared to normals was not encountered.

1. Seventy-five hundredths cc. of 1 to 1,000 epinephrin (0.75 mg.) is insufficient to result in stimulation of the anterior pituitary lobe to the secretion of increased amounts of adrenotrophic hormone.

Long et al.,<sup>2</sup> working with animals, employed 0.02 milligrams of epinephrin per 100 grams of body weight. Comparable dosage would necessitate the use of 10 milligrams in a man weighing 50 kilograms. Malmejac et al.,<sup>22</sup> working with dogs, employed 0.1 to 0.2 milligram per kilogram of body weight, intravenously every five minutes for six doses. This is equivalent to 5 to 10 mg. every five minutes in a man weighing 50 kilograms. They found that with this dosage the lymphocytes fell to two-thirds the initial value.

2. The effect is not demonstrable within five hours.

This is rather unlikely, since White and Dougherty<sup>1</sup> demonstrated the effect of adrenotrophic and adrenocortical hormone in one hour, even though the maximum effect occurred in nine hours. Long and Fry<sup>2</sup> produced adrenal changes within two hours after the administration of epinephrin, while Malmejac et al.<sup>22</sup> noted maximum effects in two to three hours.

3. In patients with Addison's disease there is still some responsive adrenal cortical tissue.

It is obvious that all grades of adrenal insufficiency both quantitatively and qualitatively exist. The lymphocyte effect is believed to depend on the carbohydrate regulating fraction of the adrenal cortex. It is possible that in clinical Addison's disease sufficient responding adrenal cortical tissue is present to react following the administration of epinephrin, with some resulting resemblance to the normal reaction.

4. The extraneous effects of epinephrin may mask its effect on the pituitary-adrenal relationship. This possible effect of epinephrin on contraction of the spleen, hemoconcentration, redistribution of formed elements in the blood may interfere with the detection of the effect being studied.

#### SUMMARY

Ten normal subjects and 11 patients with Addison's disease were studied as to their leukocyte response following the subcutaneous administration of epinephrin. The pattern of response was found to be similar in both groups, diphasic curves being noted. In general, the patients with Addison's disease differ from normal individuals in having (1) a lower and less labile white count, (2) a lower and less labile neutrophile count, (3) a higher lymphocyte count, (4) a slightly lesser percentage fall in absolute number of lymphocytes, and (5) a higher lymphocyte percentage.

The use of this method to demonstrate adrenal cortical destruction is not feasible with the dosage of epinephrin employed in this study.

# STUDIES OF BLOOD PASSED THROUGH AN ARTIFICIAL KIDNEY

By NANNIE K M DE LEEUW, M D, AND A BLAUSTEIN, M D

THE USE of the artificial kidney offers a new method of dealing with acute uremia. Many case reports, including some of our own,<sup>1</sup> attest to its value and undoubtedly with time it will be used with greater frequency.

One striking feature is the exteriorization of the patient's blood in an artificial system. The purpose of this investigation was to observe any quantitative or qualitative changes in the formed elements of the blood, that might occur in the use of the artificial kidney. Our studies were *in vitro*.

## MATERIALS AND METHODS

1. The artificial kidney used was the Kolff model.<sup>2-3</sup> Briefly, the blood is directed from the radial artery through a cannula via a system of rubber tubing and a rotating coupling into cellophane tubing approximately 30 meters in length (fig. 1). The latter is wrapped around a rotating drum, which is partially immersed in dialyzing fluid. The blood is then pumped through a Beck pump (fig. 2) which directs it into an airtrap and aids in its return into an antecubital vein.

The dialyzing fluid is heated by an electric element. The machine is provided with varnished metal splashboards, which are partially immersed in the dialyzing fluid.

The principle of the machine is that during the exteriorization of the blood, waste products dialyze out into the surrounding fluid by a process of ultrafiltration.

2. The following influences had to be considered in relation to blood changes:

*Heparin.* In our experiments a concentration of approximately 1 mg. of heparin per 10 cc. of blood was used.

*Cellophane.* The cellophane tubing used was a pure cellulose, to which a small amount of glycerin was added as a softening agent. The cellophane was boiled for ten minutes and thoroughly rinsed with normal saline prior to its use.

*Dialyzing fluid.* The dialyzing fluid consisted of 100 liters of tapwater to which was added 1500 grams of glucose, 600 grams of NaCl, 200 grams of NaHCO<sub>3</sub>, and 40 grams of KCl.

The electrolyte pattern is expressed in the Gamble diagram comparing the blood plasma and the dialyzing fluid (fig. 3). The dialyzing fluid is hypertonic ( $\pm 350$  milli-osmols) as compared with the plasma ( $\pm 310$  milli-osmols).

The temperature of the dialyzing fluid was kept approximately at 100 F.

*Rotation of the drum.* The drum rotated at 26 revolutions per minute.

*Time.* The factor of time was studied in relation to the influence of rotation of the drum and heparinization.\*

*Pump.* The influence of the pump was studied in relation to hemolysis.

*Splashboards.* The influence of the splashboards (galvanized iron and aluminum) on the pH of the dialyzing fluid was investigated in relation to hemolysis.

3. *Errors of methods.* The instruments used were all standardized: Wintrobe hematocrit tubes, Bureau of Standards erythrocyte and leukocyte pipets and a Beckman pH meter. The Rees-Ecker method was used for platelet determination. The coverslip method was chosen for our differential studies.

In our calculations we considered as significant only those erythrocyte counts that differed 12 per cent, leukocyte counts that differed 20 per cent, and platelet counts that differed 30 per cent (in the high counts) and 40 per cent (in the low counts).<sup>4-6</sup>

From the Departments of Surgery and Hematology, Royal Victoria Hospital, Montreal, Quebec, Canada.

This work was supported by a grant from the Archibald Fund.

\* In *in vivo* work it was noted that it took approximately four minutes for the blood to circulate from the arterial end to the venous end of the drum.

In differential counts, 200 leukocytes were counted and the  $\sqrt{n p q}$  theorem was used for standard deviation (according to Plum and Barnett<sup>4</sup>) the maximum error being three times the standard deviation

FIG 1 —SCHEMATIC DIAGRAM OF ARTIFICIAL KIDNEY

FIG 2a —BECK PUMP

FIG 2b —BECK PUMP (Fig 34 in De Kunstmatige Nier Profefschrift, Kampen Holland holf W J Permission of the publisher)

According to Wintrobe<sup>7</sup> the technical errors in hematocrit readings on freshly drawn blood are seldom greater than 2.5 per cent. However, in our own experiments it is possible that somewhat larger errors may have occurred as a result of the alterations in size and shape of the red cells which probably occurred during dialysis and rotation.

4. *Materials* Blood samples were taken from 6 patients without blood dyscrasia, 10 healthy nurses and doctors, 10 healthy donors of the blood bank.

## IN VITRO EXPERIMENTS

## Method

The artificial kidney was set up in the manner used for *in vivo* work. Approximately 20-30 cc of blood was taken from a volunteer, 2-3 mg of heparin was placed in the syringe prior to the venipuncture. Divided samples were then used. Samples of the heparinized blood were kept in test tubes and initial blood studies were carried out (table 1, column I), and determinations repeated after 30-60 minutes (column II). Samples of the same blood were placed in segments of cellophane tubing, 50 cm in length, which were then closed at both ends and suspended in the dialyzing fluid for 15-25 minutes (column III). Other segments of cellophane tubing of the same length were filled with approximately 10 cc of

FIG 3—COMPARISON OF BLOOD PLASMA (LEFT) AND DIALYZING FLUID (Chart 34 in *Extracellular Fluid* by J. L. Gamble Cambridge 1942. Permission of the author)

blood, attached to the drum and rotated for 3-8 minutes (column IV), and 15-25 minutes (column V).

We were able to observe the influence of rotation of the drum by comparing the results of the rotated samples with those obtained from the suspended blood samples. By further comparing the last findings with those of the control samples of heparinized blood the effect of the dialyzing fluid, the cellophane and the rinsing fluid was determined. Comparison of the initial and the second determinations on the control samples allowed us to surmise the possible effect of heparin on the formed blood elements. Our studies were confined to red blood cell counts, hematocrit readings, white blood cell counts, platelet determinations and differential counts of the leukocytes.

The results of these determinations are summarized in table 1.

*Interpretation* Comparing columns I and V significant changes were found in hematocrit readings, but only in two red blood cell counts. There was a significant

change in all leukocyte and platelet counts. A great number of factors could account for these changes, and therefore we made the following differentiation

TABLE I

Italic figures = Significant difference. ( ) = time in min.

i. Comparison of columns I and II allows for the interpretation of the influence of heparin for a certain period of time. No significant changes were found in hemato-

crit readings (with one exception), red blood cell counts, white blood cell counts and platelets after thirty minutes

2. Comparing columns III and V, from which the effect of *rotation* of the drum on the blood samples can be determined, a significant drop in the leukocyte and platelet count was found. A slight change in hematocrit determinations was noted, but not in the red cell counts

3. Comparing columns IV and V, in which the influence of the *time* factor on rotation of the drum can be determined, slight changes were found in the hematocrit determinations, but not in the erythrocyte counts. A decided drop in the leukocyte and platelet counts was evident

4. Comparison of the columns II and III allows for the interpretation of the influence of *dialyzing fluid*, *cellophane* and *rinsing material*. In 2 cases, there was a drop in the hematocrit value. There was no significant change in the erythrocyte, leukocyte or platelet counts

5. Comparing columns III and IV, it is apparent that the leukocyte count dropped only in two blood samples through the influence of rotation for a period of three minutes

6. Studies of differential smears were made in order to observe whether the drop in the leukocyte count, noted in column V, was uniform. The smears in all cases, revealing a normal differential picture, did not significantly change in the different blood samples. In the smears made from the blood samples of columns III, IV and V condensation of the nuclei and vacuolization of the cytoplasm with ameboid cell outlines were seen in the granulocytes. Most of the monocytes were vacuolated. The number of hypersegmented polymorphonuclear leukocytes in column V ranged from 7-15 per cent of the total leukocyte count in three out of six cases

*Conclusions* Studies of our control samples reveal that heparin does not exert any significant influence on the erythrocyte, leukocyte and platelet counts in a thirty minute period at room temperature. Rotation of the drum for a period of three minutes sometimes results in a significant drop in the leukocyte count, after a fifteen minute period a decided drop in the leukocyte and platelet count becomes evident. The dialyzing fluid and the rinsing material appear to cause some dilution, as seen in the decrease in hematocrit values after suspension, but more marked after rotation of blood samples in cellophane tubing

#### *The Effect of Dry Cellophane on in Vitro Dialysis*

Segments of cellophane tubing, 50 cm. in length, were boiled, rinsed with saline, dried, and then 5 cc. of heparinized blood was placed in each. Some segments of cellophane tubing filled with heparinized blood were suspended in the dialyzing fluid, others were rotated on the drum for a certain period of time. Results show (table 2) that hemoconcentration or hemodilution may occur, if samples of dry cellophane tubing are used in in vitro dialysis

#### *The Chemotactic Influence of Cellophane on Granulocytes*

In order to investigate the possible chemotactic influence of cellophane on the leukocytes, white blood cell counts were done on samples of heparinized blood,

placed in sterile test tubes in which sterilized strips of cellophane were immersed for a period of one hour, and the results compared with the counts obtained from control samples of blood

*Procedure* Strips of cellophane, 10 cm in length, were boiled, rinsed with large amounts of normal saline, and were dried and sterilized 15 cc of blood was taken under sterile conditions from a donor and divided among three sterile test tubes, each containing 15 mg of heparin Test tube I was used as a control and did not contain cellophane A strip of the sterilized, dried cellophane was placed in test tube II The blood in test tube III was used for initial hematologic determinations Test tubes I and II were stoppered and immersed in a waterbath of approximately 100 F, and white blood counts were done one hour later The results are shown in

(β)	P L.	M	N H	4,950	3,050	4,250
(γ)	F C.	M.	N H.	3,950	4,000	6,750

table 3 Differential counts done on samples (β) and (γ) showed no significant changes after one hour as compared with the initial counts

In tests (β) and (γ), two strips of cellophane were immersed in the tubes (II) In test (γ), the heparin concentration was twice as high as in the other tests, which might be responsible for the greater drop of the leukocytes in both tubes

Segments of cellophane, taken after one hour, and stained with Wright's stain, were coated with leukocytes A control piece of cellophane, taken after ten minutes immersion in the blood, showed only a few leukocytes (figs 4a and b (control))

*Conclusion* A definite drop of leukocytes can be seen in two of the three blood samples in which cellophane strips have been immersed for one hour, and in one of the control blood samples after one hour Therefore, we cannot conclude from the white blood counts, that cellophane has a positive chemotactic influence on

FIG 4a —CHEMOTACTIC INFLUENCE OF CELLOPHANE ON GRANULOCYTES See TEXT

FIG 4b —CHEMOTACTIC INFLUENCE OF CELLOPHANE ON GRANULOCYTES See TEXT.

the leukocytes. However, the vast number of granulocytes present on the sterile strips of cellophane is at least indirect evidence of an attractive influence exerted by the cellophane, almost exclusively for the granulocytes.

### *The Influence of Heparin and Cellophane on the Platelets*

The same test was done as the one just described, but under unsterile conditions, and platelet counts were made from tubes I and II (without and with cellophane) at different intervals (see table 4). It can be seen that the counts dropped equally in both tubes. In the stained smears the platelets were clumped and appeared swollen and disintegrated in the one and two hour samples, and were diminished in number. After two hours the cellophane strips showed large clumps of platelets.

*Conclusion* This concentration of heparin (approximately 1 mg./10 cc. of blood) cannot prevent platelet agglutination. Disintegration of the platelets starts after about half an hour.

*Note* There were also clumps of platelets to be seen on the control strips of cellophane after 10 minutes in the preceding test (chemotactic influence of cellophane on granulocytes).

			100,000	90,000	120

### *Hemolysis*

Hemolysis was commonly noted in all samples of blood subjected to the rotation of the drum. Hemolysis being an important feature, it was decided to investigate possible causes.

### *The Role of Cellophane*

1. Twelve test tubes, each containing 5 cc. of heparinized blood, were set up in a rack. Four were used as controls and did not contain cellophane. Four contained strips of cellophane that had not been boiled or rinsed, and four contained strips of cellophane that had been boiled and rinsed twice with saline and then dried. All tubes were allowed to stay at room temperature for thirty minutes. The control tubes showed no hemolysis, the tubes containing unwashed cellophane showed hemolysis, varying from a trace to one plus, those containing the washed cellophane all showed a trace of hemolysis. Fresh smears of all of these samples did not reveal spherocytosis (table 5).

2 Cellophane tubing, 300 cm in length, was boiled and rinsed with 10 liters of normal saline. Segments, 30 cm in length, were cut and filled with 5 cc of heparinized blood each. These segments were then suspended in a bath of saline at 84-89 F for half an hour. The above was repeated, using segments of cellophane

that were not rinsed with saline. The latter samples of blood revealed a slight to marked hemolysis in all cases, whereas the former showed no hemolysis at all (table 6).

3 Similar experiments, suspending three samples in the dialyzing fluid rather than in saline, did not show any hemolysis in two of these cases. There was a trace of hemolysis in the third case (table 6).

*Role of the Dialyzing Fluid*

Heparinized blood, 5 cc, was added to two test tubes each containing 1 cc of dialyzing fluid. No hemolysis or spherocytosis was to be seen after two hours.

*The Factors of Time, Rotation of the Drum, Length of Cellophane Tubing, Amount of Blood and Temperature of the Dialyzing Fluid*

Samples of blood were placed in cellophane tubing, which was boiled, rinsed with 10 liters of saline and dried prior to its use. The segments were then attached to the drum. The above factors were all varied and their influences studied (table 7). Hemolysis occurred in all samples of blood rotated on the drum. In two of the four samples, hemolysis was more marked after rotation for fifteen minutes rather

than three minutes. Less hemolysis occurred when the cellophane tubing contained a larger amount of blood. In two cases studied, there was less hemolysis with increase of temperature of the dialyzing fluid (109 F) as compared with samples rotating at 90 F.

*Role of the Pump*

Samples (5 cc) of heparinized blood were placed in a circuit of rubber tubing and sent through the pump for periods of one and three minutes. Samples were then centrifuged in test tubes and in all cases there was slight hemolysis. No changes were found in hematocrit determinations, erythrocyte, leukocyte and platelet counts after three minutes (table 8).

*Handling of the Cellophane*

Experiments were carried out to determine whether the handling of the cellophane containing the blood influenced the occurrence of hemolysis. Hemolysis appeared to be more marked in those samples of blood that were handled

*pH of the Dialyzing Fluid*

Determinations of the pH of the dialyzing fluid were made before and after experimental use of the artificial kidney. The pH increased after *in vitro* use of the artificial kidney for about six hours (table 9). It was thought that the metal splashboards might alter the pH of the dialyzing fluid, and pH determinations were carried out in experiments where the splashboards were not used. It appeared that the immersion of these in the dialyzing fluid resulted in a rise in the pH (table 9).

## DISCUSSION

*Erythrocytes*

Some dilution of the blood occurs as a result of the passage of the dialyzing fluid through the cellophane in suspended and in rotated blood samples. The possible presence of some of the rinsing fluid in the cellophane tubing may also account for some of the dilution which is evident through the decreased hematocrit values. The discrepancy between hematocrit and red blood cell values may be related to the shrinkage of the cells in hypertonic medium.

*Leukocytes*

Wilander,<sup>8</sup> Jorpes,<sup>9</sup> and Lucia and Aggeler<sup>10</sup> noted that heparin causes *in vitro* agglutination and disintegration of leukocytes after one hour. In some of our *in vitro* studies using heparinized blood, we were able to observe this phenomenon in our two hour blood samples. No change could be found after half an hour. In our experiments in which samples of blood were suspended in the dialyzing fluid

or rotated on the drum the time never exceeded 15-25 minutes, and therefore we were not able to judge the role of heparin in these experiments

The cellophane used was a pure cellulose. Cellulose, according to Chambers and Grand,<sup>11</sup> exerts positive chemotaxis on granulocytes. We have demonstrated that strips of cellophane suspended in sterile test tubes containing heparinized blood become thickly coated with granulocytes after one hour. The total white blood counts and the differential counts of those blood samples were not significantly altered as compared with control samples of blood, but this is probably related to the fact that chemotaxis does not occur beyond a distance greater than one millimeter, so that with a sample of blood in a test tube no appreciable change in the above values is to be expected.

In our samples of blood that were rotated on the drum, the time factor is important, since the period did not exceed twenty-five minutes in any of these experiments, and, according to Dixon and McCutcheon,<sup>12, 13</sup> it takes at least thirty minutes for the leukocytes to develop their normal rate of locomotion. Stained sections of cellophane from the rotated samples of blood did not reveal an increase of granulocytes. From our chemical determinations we know that glucose crosses the cellophane barrier and enters the blood (samples of kidney blood contain approximately 1400 mg per cent glucose). Chambers and Grand<sup>11</sup> have demonstrated the positive chemotactic influence of glucose on the granulocytes. The granulocytes, therefore, may be in a position of *embarras du choix*.

*Rotation of the drum.* Dilution and the damaging action of slow speed centrifugation probably account for the drop in the leukocytes in the samples of blood rotated on the drum, a drop which is increased with time.

Hypersegmentation of the polymorphonuclear leukocytes was frequently seen in those samples that rotated on the drum for fifteen minutes. Oria<sup>14, 15</sup> has observed hypersegmentation in oxalated and centrifugated blood samples and Ponder<sup>16</sup> in heparinized blood that has been exteriorized for some time. Exteriorization and slow centrifugation may have played a role in our cases.

### *Platelets*

The drop in the platelet count in the suspended samples of blood and in the samples rotated on the drum can be accounted for by dilution, the presence of rough surfaces offered by the cellophane tubing, and the mechanical damage of rotation on the drum. Solandt and Best,<sup>17</sup> Baronofsky and Quick<sup>18</sup> state that large doses of heparin prevent platelet agglutination. The concentration of heparin we used fell below these requirements.

### *Hemolysis*

This phenomenon is of clinical importance in the use of the artificial kidney. Heparin and the dialyzing fluid have no hemolytic action. The cellophane used was a pure cellulose, but had glycerin added as a softening agent. Our experiments proved to us that the cellophane had to be thoroughly rinsed with at least 10 liters of normal saline prior to its use, as advised by Kolff<sup>2, 3</sup> in order to wash away the glycerin which is known to be hemolytic even in small quantities (van Noordwijk<sup>2, 3</sup>).

Rotation of the drum causes hemolysis within four minutes, and the degree of hemolysis increases with time. Handling of the cellophane tubing containing blood demonstrates hemolysis. Blood, subjected to the influence of the pump used in aiding venous return, demonstrated hemolysis within the period of one minute. According to our calculations, during an *in vivo* dialysis of six hours each cc of blood is compressed approximately forty-five times by the rollers of the pump. This is the degree of mechanical injury to which 1 cc of blood was subjected for one minute during our test (each cc being compressed forty-five times by the rollers of the pump during the period of one minute). Therefore, in all probability, during *in vivo* dialysis the action of the pump partly accounts for the occurrence of hemolysis, although it is realized that the studies of hemolysis in relation to the pump are not entirely comparable with the role of the pump in *in vivo* dialysis. The role of high temperature as a cause of hemolysis is well known.<sup>4</sup> In our experiments we did not elevate the temperature of the dialyzing fluid above 109 F, and at that level we did not notice any increased hemolysis.

According to Ponder<sup>4</sup> and Gordon,<sup>19</sup> an extremely high pH and an extremely low pH will act directly on the red cell giving hemolysis. The pH of our dialyzing fluid at no time reached these levels. The metal splashboards may have contributed in altering the pH of the dialyzing fluid. The varnish does not last very long and therefore appears to be no protection against the ionization from the splashboards. The metals used (Zn and Al) do not belong to the group which has hemolytic action in high dilutions.

Kolff<sup>2, 3</sup> demonstrated that rapid rotation of the drum (at 35 revolutions per minute) produces hemolysis. We used a speed of 26 revolutions per minute and also observed hemolysis. Glucose 1.5 per cent added to the dialyzing fluid could not prevent hemolysis in rotating blood samples.

#### *Measures to Minimize Hemolysis*

The cellophane tubing should be boiled in a large amount of water and then carefully rinsed with 10 liters of sterile saline in order to remove the glycerin.

Glucose, 1.5-2 per cent, should be added to the dialyzing fluid in order to inhibit hemolysis.<sup>2, 3</sup>

Alcohol or ether should not be used in mounting the artificial kidney.

Do not use soap in cleaning the enamel bath.

The temperature of the dialyzing fluid should be approximately 100 F.

Handling of the cellophane tubing with the flat hand, in order to push the blood forward, should be avoided.

Avoid unnecessary rotation of the drum during *in vivo* dialysis.

Splashboards should be made of nonhemolytic material. Metal should not be used.

#### SUMMARY

1. *In vitro* blood studies using the artificial kidney are discussed in detail.

2. *In vitro* experiments in which samples of blood in cellophane tubing are rotated on the drum showed a diminution in the red cell volume, leukocyte and platelet counts.

Dilution, caused by the passage of the dialyzing fluid through the cellophane membrane and by the presence of some of the rinsing fluid, and rotation of the drum are factors of importance in this regard

3 The influence of heparin and the chemotactic role of cellophane on the leukocytes are discussed

Heparin in concentration of 1 mg / 10 cc of blood causes in vitro agglutination and disintegration of leukocytes after approximately one hour

Photographs are shown that demonstrate coating of the cellophane by granulocytes This is in keeping with the findings of Chambers and Grand that cellophane exerts a positive chemotactic influence on the granulocytes

4 Hypersegmentation of the leukocytes was noted in samples of blood rotated on the drum for fifteen minutes Exteriorization and slow speed centrifugation probably account for this phenomenon

# A METHOD FOR ISOLATING LIVING POLYMORPHONUCLEAR LEUKOCYTES FROM PERIPHERAL BLOOD

By ALLEN H. MINOR, M.D.,\* AND LEE BURNETT, M.S.

THE LIVING polymorphonuclear leukocyte can readily be obtained without significant trauma either to the cell or to its donor. The movement of its granules, as seen with darkfield illumination<sup>1</sup> or supravital staining,<sup>2</sup> affords a visible index of its vitality. These attributes render this cell particularly suitable for cytologic studies. In order to facilitate such studies, we have developed a method for isolating living polymorphonuclear leukocytes on a microscope slide. This method takes advantage of two properties inherent in blood components: the ability of fibrinogen to accelerate erythrocyte sedimentation,<sup>3</sup> and the adhesive quality of living polymorphonuclear leukocytes.<sup>4</sup>

## METHOD

The method used for cell isolation consists of two steps. In the first step, the ratio of erythrocytes to leukocytes is reduced from about 800:1 in normal blood to nearly 1:1. This is accomplished by the addition of fibrinogen to heparinized blood. By this means the erythrocyte sedimentation rate is so accelerated that within an hour essentially all the erythrocytes have settled out, leaving essentially all the leukocytes suspended in the supernatant plasma.<sup>5</sup>

In the second step, polymorphonuclear leukocytes are isolated on a slide from all other cells in the plasma suspension. This is accomplished by means of the adhesiveness of these cells to a solid surface. When the suspension is placed in a vessel similar to that described by Fenn,<sup>6</sup> consisting of a glass ring on a microscope slide, and the blood cells are permitted to sediment, subsequent washing of the slide removes the plasma and all cells except adherent polymorphonuclear leukocytes.

The following technic for this step has been found practical:

1. Place one or more glass rings 3 mm. high by 15 mm. internal diameter on a microscope slide. Press modelling clay against the angle formed by the slide with the exterior of the rings. The clay prevents leakage, appears to be nontoxic, and subsequently may easily be removed from the slide.

2. Pipet 0.3 ml. leukocyte suspension into each of the vessels so formed, cover with a glass slide or coverslip, and incubate at 37°C. for one hour. Suspensions in which the concentration of polymorphonuclear leukocytes is considerably greater than normal may first be diluted with plasma.

3. Immerse the vessels in a 250 ml. beaker filled with normal saline or other physiological solution at room temperature. Remove the rings, taking care to avoid contact with the spots of cells on the slide. Then move the slide back and forth in the fluid a few times. This removes nonadherent cells from the slide, leaving only polymorphonuclear leukocytes.

This work was begun at The Sloan Kettering Institute for Cancer Research, New York, N. Y., and completed at The Lenox Hill Hospital, New York, N. Y.

\* Postdoctorate Research Fellow, National Cancer Institute.

FIG 1—LIVING POLYMORPHONUCLEAR LEUKOCYTES ISOLATED FROM HUMAN PERIPHERAL BLOOD  
X 630 Darkfield illumination

#### DISCUSSION

This method for isolating polymorphonuclear leukocytes may be useful in cell studies for the following reasons

The cells obtained are of a single type This is apparent from the photomicrograph (fig 1) Reactions between these cells and their medium may be observed without the presence of other cell types

The cells are alive, and their vitality is immediately manifest. In a favorable environment, living polymorphonuclear leukocytes exhibit intracellular granular motion and amoeboid movement. These activities are indicated in the photomicrograph by blurring of the granules and irregularity of cell shape. Dynamic changes may thus be observed directly and recorded photographically.

Homologous cells may be compared. Two or more spots of cells may be prepared on a single slide. Comparisons may be made either between cells from different sources exposed to a given chemical or physical agent, or between cells from the same source exposed to different agents. Either the reactive capacities or the chemical composition of the cells may be studied.

The method is technically simple. It utilizes equipment and reagents which are readily available. There is minimal traumatization to the cells.

#### SUMMARY

A simple method is described for isolating living polymorphonuclear leukocytes from peripheral blood. It is based on the selective adherence of these cells to a microscope slide, which permits all other blood components to be removed by washing. The reasons for considering this method useful in cell studies are discussed.

#### ACKNOWLEDGMENT

The authors are indebted to Mr. Martin Shames and the King Weese Studios, New York, for the photomicrograph.

# A METHOD FOR THE RAPID SEPARATION OF LEUKOCYTES AND NUCLEATED ERYTHROCYTES FROM BLOOD OR MARROW WITH A PHYTOHEMAGGLUTININ FROM RED BEANS (*PHASEOLUS VULGARIS*)

By JONAH G. LI, M.D., AND EDWIN E. OSGOOD, M.D.

A TECHNICALLY simple and rapid method for separating living leukocytes and nucleated erythrocytes from whole blood or marrow with a high degree of efficiency, large net yield and negligible admixture with mature erythrocytes or other contaminants is needed for chemical, metabolic or cultural studies of these cells. The method presented in this paper describes a technic for accelerating the sedimentation of erythrocytes, leaving unaltered leukocytes and other nucleated cells suspended in their own plasma. This separation can be accomplished in approximately ten minutes from the time the blood or marrow specimen has been collected. It is applicable to any volume of blood from less than 10 ml. to over 500 ml.

## METHOD

*Principle* Erythrocytes are agglutinated by addition of the phytohemagglutinin, sedimented by slow centrifugation, and the supernatant fluid containing the living nucleated cells in uniform suspension is separated by aspiration.

*Technic of cell separation* Withdraw the desired amount of blood or marrow by venipuncture or sternal puncture and deposit in tubes with a measured amount of an anticoagulant. Sodium citrate, potassium oxalate or heparin are satisfactory for this purpose. Add the optimal amount of bean extract containing the phytohemagglutinin and mix. Centrifuge at about 40 g (500 rpm in an International centrifuge size 1, type S B, with No. 20354 head) for about 90 seconds or until the maximum plasma volume containing a uniform suspension of leukocytes with no buffy layer is obtained. Aspirate the supernatant plasma.

If the erythrocyte count is over 7,000,000 per cu. mm., add two volumes of pooled plasma and double the usual amount of bean extract, mix thoroughly and proceed as above. Physiologic saline is not satisfactory as a diluent for polycythemic bloods. This technic will increase the yield of nucleated cells and the percentage of erythrocytes eliminated in nonpolycythemic bloods, but is not necessary for most purposes.

*Preparation and standardization of the phytohemagglutinin* Soak 200 Gm. of dry red beans (*Phaseolus vulgaris*) or navy beans (*Phaseolus communis*) for 24 hours in 1000 ml. of 0.85 per cent sodium chloride solution at room temperature. Macerate in a Waring blender. Let the mixture stand at room temperature for three hours, stirring frequently. Centrifuge and decant the viscous extract from the bean pulp and mix it with about 10 Gm. of kieselguhr or other filter-aid. Filter the extract through Whatman No. 30 paper in a Buchner funnel with suction. This may require

From the Division of Experimental Medicine, University of Oregon Medical School, Portland, Oregon, aided by a grant from the Medical Research Foundation of Oregon, Portland, Oregon.

16 to 24 hours because of the viscosity of the extract. Adjust the pH of the filtrate, usually about 4.2, to 7.3-7.6 with 20 per cent sodium hydroxide, add filter-aid and refilter through Whatman No. 30 paper in a Buchner funnel with suction. Sterilize this filtrate by passing through a Seitz filter. The yield is approximately 300 ml.

An amorphous material of high agglutinating titer may be obtained by dialysis and evaporation of the clear fluid after removal of the precipitated globulins as described by Osborne, Mendel and Harris<sup>1</sup> if the minimal possible organic addition is desired. However, the crude extract is entirely satisfactory for the separation of nucleated blood and marrow cells and is quite stable. Two aliquots of the extract showed no appreciable loss of potency after being kept for six months at room temperature (18 to 22 C) and for nine months at refrigerator temperature (8 to 10 C).

*Titration of the extract.* Do a leukocyte count on a sample of oxalated normal human blood and calculate the number of leukocytes in each 5 ml. Add to a series of centrifuge tubes, each containing 5 ml of this blood, increments of 0.05 ml (0.05 ml, 0.10 ml, 0.15 ml, etc.) up to 0.3 ml of bean extract. Mix thoroughly and centrifuge at 500 rpm (40 g) for 90 seconds. Enumerate the leukocytes in the supernatant plasma. From the volume of the supernatant plasma and its cell count calculate the yield of leukocytes as per cent of the absolute number in the original 5 ml of whole blood. The volume of bean extract which produces the highest yield of leukocytes and the fewest erythrocytes is the optimal amount for that lot of extract. This is usually 0.1 to 0.2 ml of the extract for each 5 ml of oxalated blood. Too little extract fails to agglutinate all the erythrocytes and too much entraps some leukocytes in the large aggregates of erythrocytes produced.

*Efficiency of the separation.* Tables 1, 2 and 3 show the data obtained in evaluating the method. As shown in table 1 the phytohemagglutinin affects the erythrocytes of all blood groups equally efficiently. In bloods with essentially normal leukocyte and erythrocyte counts, a mean of 77 per cent of the total leukocytes present in the original blood were recovered in the plasma, with a range of 61 to 94 per cent. A mean of 99.82 per cent of the erythrocytes originally present were eliminated, with a range of 99.5 to 99.98 per cent. The percentage recovery shows no relationship to the initial leukocyte or erythrocyte counts.

Note from table 2 that 52 to 78 per cent of the leukocytes of leukemic bloods with high cell counts were recovered and over 99 per cent of the erythrocytes present in the original blood were eliminated. There appear to be no significant differences in the recovery of leukocytes from the different types of leukemia. It is shown in table 3 that when the technic recommended for polycythemic bloods was employed 60 to 100 per cent of the leukocytes were recovered and over 99 per cent of the erythrocytes were eliminated.

Cell separations carried out by this technic on marrows from patients with marked hyperplasia of the erythrocytic series of cells have shown comparable recoveries of the total nucleated erythrocytic cells with proportions of each nucleated erythrocytic stage similar to those in the original marrow as shown by differential counts of smears prepared before and after cell separation. It is obvious,

therefore, that the phytohemagglutinin does not agglutinate nucleated erythrocytes in appreciable numbers even when they have developed their full complement of hemoglobin. Reticulocyte counts from the supernatant fluid indicate that the proportions of reticulocytes in the few remaining erythrocytes are somewhat increased, but that the majority of reticulocytes are eliminated.

### DISCUSSION

*Properties of the phytohemagglutinin* Although we rediscovered this phytohemagglutinin accidentally and independently, search of the literature revealed that Dorset and Henley<sup>2</sup> in 1916 used a crude extract of navy beans (*Phaseolus communis*) in the large scale preparation of antiserum for hog cholera. Goddard and Mendel<sup>3</sup> in 1929 thoroughly investigated the properties of the phytohemagglutinin isolated from navy beans, described a technic for preparing it in purified form and showed that it agglutinated human, rabbit, dog, mouse, chicken, duck and rat erythrocytes. It differs from concanavallin-A<sup>4</sup> in that it agglutinates human erythrocytes and from ricin<sup>1</sup> in that it is nontoxic. We have cultured leukocytes and nucleated erythrocytes isolated by this technic, using the marrow culture method,<sup>5, 6</sup> and have noted no detectable effects on the morphology, survival, mitosis or motility of the cells. Goddard and Mendel<sup>3</sup> injected 8 mg. of their purified material per kilogram of body weight into rabbits and 600 mg. per kilogram of body weight into mice with no demonstrable deleterious effects. This lack of toxicity clearly shows that it is not ricin, which is one of the most toxic substances known. Goddard and Mendel<sup>3</sup> concluded from their studies of the purified material that it is a water-soluble albumin. They found that 0.7 micrograms of the purified material would completely agglutinate 0.5 ml. of a 2.5 per cent suspension of human erythrocytes in isotonic saline. We found that 0.1 mg. of the purified material was optimum for agglutination of the erythrocytes in 1 ml. of normal blood. Use of the purified material is necessary only if the minimal amount of contamination by extraneous organic material is essential in the studies for which the isolated leukocytes are to be used.

*Comparison with other methods* The usual method of separation of leukocytes and nucleated erythrocytes by prolonged centrifugation to concentrate them in a layer has several disadvantages. Among these are the contamination of the leukocytes by erythrocytes, the low yield of 30 to 50 per cent and the clumping which prevents accurate cell counts.

A number of methods have been reported recently designed to overcome these disadvantages. None of these, however, introduces so little extraneous organic material, gives such consistently satisfactory cell separations and leaves the nucleated cells in both a countable and viable condition. In none of the other reports are adequate data given from which to calculate the percentage yields of nucleated cells. None of these reports describes the separation of nucleated erythrocytes.

Of these methods the technic described by Valec, Hughes and Gibson<sup>7</sup> of flotation of leukocytes on salt-free albumin of specific gravity 1.079 appears to be the best. This method is not suitable for processing large volumes of blood. The adjustment of specific gravity of the albumin solution has to be very critical and somewhat different for different blood or marrow specimens. Cells at the albumin-

plasma interface are exposed to high colloid osmotic pressures and may be markedly shrunk and the cells are no longer countable because of matting together. One can never be certain what the yield is on the particular blood or marrow specimen under study. We have found difficulty with this method in getting uniform, complete separation of the nucleated and non-nucleated cells, although under ideal conditions it probably gives the highest percentage yield of any method yet described.

The method of Spear<sup>8</sup> uses the same flotation principle and has the same advantages and disadvantages as the preceding method plus the necessity of freeing the cells from the gum acacia used and the technical difficulty of adjusting the solution to proper pH, tonicity and specific gravity. It is much more time-consuming than the method here presented.

The method of Singer, Silberbach and Schwartz<sup>9</sup> depends on hemolysis of the erythrocytes by a mixture of gramicidin and lysolecithin. Free hemoglobin is known to be toxic to cultures of living cells. Intensive washing of a highly viscous mixture is necessary to free the nucleated cells from hemoglobin. It seems highly probable that these surface active substances might damage the cytoplasmic membranes of leukocytes as well as erythrocytes.

The method of Minor and Burnett,<sup>10</sup> which depends on production of rouleau formation by addition of fibrinogen from fraction I of human plasma, appeared after this study was completed. While no studies of the yield obtained were reported, our work with the method indicates that if modified by the use of the centrifugation technic herein outlined satisfactory cell separation is obtained. It would be much more expensive if the fraction I were sold at cost of production. It also introduces larger amounts of extraneous organic and inorganic materials than the method described in this paper.

#### SUMMARY

A method is described for rapid and efficient separation of leukocytes and nucleated erythrocytes from blood or marrow. It is based on the rediscovery of a non-toxic hemagglutinin, isolated from common red or navy beans, which agglutinates all human erythrocytes and those of the animals which have been tested with it. The time from drawing the blood to complete separation of the cells is less than ten minutes. The cells remain in suspension in their own plasma and are countable. Negligible amounts of foreign material are introduced, a great advantage in chemical studies. The cells so isolated are living and suitable for culture studies. Any volume of blood from less than 1 ml. to over 500 ml. may be processed. In marrow nucleated erythrocytes are separated with the leukocytes and in their original proportions. The volume, motility, morphology and life span of the cells in cultures are not altered by addition of the bean extract.

## HEMOLYTIC ANEMIAS

HAEMOLYTIC DISEASE OF THE NEWBORN CRITERIA OF SEVERITY P. L. Mellison and Marie Catbush From the Medical Research Council Blood Transfusion Research Unit Department of Obstetrics Post graduate Medical School, London Brit M J 1 123 1949

The hemoglobin value of cord blood is well correlated with the severity of hemolytic disease. In contrast venous and capillary blood samples especially when taken some hours or days after birth are liable to misinterpretation. Normal values do not exclude anemia at birth. If the cord is not clamped early and transfer of placental blood is allowed, a deceptively high hemoglobin value may result.

In this series most of the babies with a cord hemoglobin of less than 8 grams per cent died within twenty four hours of birth. A raised venous pressure found in some of these infants suggested that they died from heart failure. All of those with a cord hemoglobin of over 14 grams per cent survived.

The cord bilirubin and degree of erythroblastemia also show some correlation with severity of the disease but other tests such as the strength of the direct Coombs test amount of free antibody in the infants blood and form of antibody in the mothers serum are of limited value.

These observations are of considerable value as a guide to the management of infants with hemolytic disease. Also, as the authors point out the adoption of examination of cord blood as a routine in affected babies would make it possible to compare groups of cases in regard to severity.

S.C.

MEDITERRANEAN ANEMIA A. Marmont and V. Bianchi From the University Medical Clinic Geneva (Italy) Acta haematologica 1 4-18 1948

Three cases in the same Sicilian family of the so-called Rietti-Greppi Micheli's hemolytic anemia with increased osmotic resistance of the erythrocytes are reported remarkable also for the clinically and hematologically normal parentage. The genetic implications related to this point are discussed. The findings of a biliary calculus and an ulcer on the right ankle of one of them are briefly elucidated. Hematologic studies showed the well known features of this peculiar disease particular stress is laid on the authors' researches on red cells fragmentation *in vitro* and *in vivo* chiefly by means of a supravital staining technique and others.

The demonstration of an intense erythrocytic disintegration with signs of increased mechanical fragility, both in this and in genuine Cooley's anemia affords still a further motive to the authors for identifying the above mentioned syndrome with the moderate form of Mediterranean anemia. The hypothesis of mechanical fragility as closely related to increased osmotic resistance and inversely to osmotic fragility is considered and an outline of a new classification of primarily hemolytic and primarily erythrocytic anemias the latter comprising both thalassemia and sickle-cell anemia is put forward. Some

speculations as to the nature of the blood disorder suggesting a congenital error of iron metabolism possibly involving faulty stromato-hemoglobin bindings, are advanced

C M

**CONGENITAL HEMOLYTIC ICTERUS IN THE NEGRO** R. R. McCormack and E. P. Simon From the Department of Medicine, Cornell University Medical College and the Second (Cornell) Medical Division Bellevue Hospital New York City *Am J M Sc* 216 539-544 1948

Congenital hemolytic icterus in a 16 year old Negress is reported. This patient is a maternal aunt of the patient reported by Scherer and Cecil (*J Lab & Clin Med* 30 244 1945) and if the diagnosis is correct is about the fourth or fifth well authenticated case reported in a Negro. No evidence of racial admixture was obtained. The diagnosis of congenital hemolytic icterus was supported by the family history, spherocytosis, splenomegaly, and increased erythrocyte fragility in hypotonic saline. However history of hemolytic episodes was singularly lacking, the anemia and reticulocytosis were minimal and although jaundice was present it was most likely due to the passage of a common duct stone. Following splenectomy and cholecystectomy the jaundice disappeared, the spherocytes diminished in numbers the saline fragility curve shifted toward normal and the reticulocytosis, macrocytosis and anemia disappeared.

G E C

**THE SICKLE CELL TRAIT: INCIDENCE AND INFLUENCE IN PREGNANT COLORED WOMEN** P. K. Switzer and H. H. Fowble From the Departments of Medicine and of Obstetrics and Gynecology of the Medical College of the State of South Carolina and of the Roper Hospital *Am J M Sc* 216 330-332, 1948

The sickle cell trait was found in 14.2 per cent of 500 gravid Negro women, in 14 per cent of 250 nongravid Negro females of child bearing ages, and in 13.8 per cent of 250 adult Negro males. Of 71 pregnant females with the sickle cell trait, one was found to have mild sickle cell anemia. Sickle cell anemia did not interfere with conception nor with normal pregnancy and delivery. Pregnancy did not activate a blood destructive process in 21 sickle cell patients observed through the last trimester and during labor and the puerperium.

G E C

**HAFS DISEASE IN SWEDEN** R. Berlin From the Medical Department of the Lidköping County Hospital Lidköping, Sweden *Acta med Scandinav* 129 560 1948

The disease observed by Berlin in 11 cases from Central Sweden has previously never been observed outside East Prussia. It was first described in 1924-25 and later in 1932-33 with in all about 1000 cases. Even if the disease itself is hardly to be regarded as belonging to hematology the sudden appearance of large amounts of blood pigments in the urine should make it of diagnostic importance especially to hematologists.

The symptoms appear some time after the patient has eaten fish and occur chiefly among fishermen. In the present epidemic all the patients lived around a lake where the fishing is of great economic and nutritional importance. All the cases occurred from February 1942 to April 1943. Later there were no similar cases. The symptoms are always ushered in by pains in the legs and back, the urine is dark red and contains large amounts of myoglobin. After some days the pains disappear and the urine becomes pale. Uremia is the only complication and in the author's material there were 2 deaths among 11 persons.

The author discusses the possibility that the disease may have something to do with the so-called Chastek paralysis caused by the presence of an antithiamin active substance in the muscles from certain fish species.

It seems probable that this diagnosis will be found to be more common with increasing knowledge of the symptomatology.

**DIFFERENTIAL DIAGNOSIS OF HEMOLYTIC ANEMIAS** H. Ludin From the Medical University Clinic Basel (Switzerland) *Acta haematologica* 1 28-33 1948

The paper reports on the determination of the life duration of transfused red cells in two cases of hemolytic anemia, one of these cases belonged to macrocytic anemia, Dyke Young, the other was a case

of congenital hemolytic jaundice. The conclusions which can be drawn from these investigations for the pathogenesis of such types of anemia are discussed

C.M.

A CASE OF LYMPHOGRANULOMATOSIS (HODGKIN'S DISEASE) WITH HEMOLYTIC ANEMIA *Svend Grønlund*  
From the Medical Department of Aalborg County Hospital, Denmark. *Acta med Scandinav* 129: 361, 1947

The occurrence of hemolytic anemia (hypersplenism) in patients with splenomegaly from different causes is well known at present. The case treated in this paper is of great interest as splenectomy caused temporary improvement of the anemia (erythrocytes from 0.84 mill to 3.5 mill). Later the patient developed typical Hodgkin's disease with involvement of the lymph glands. Histologic structure was typical in the glands but the microscopic examination of the spleen showed no sign of Hodgkin's disease. Two similar cases have been published previously. Such instances of symptomatic hypersplenism are of great therapeutic importance as has recently been emphasized by Dameshek.

## MACROCYTIC ANEMIAS

MACROCYTIC ANEMIA IN CENTRAL AFRICANS IN RELATION TO ANCYCLOSTOMIASIS AND OTHER DISEASES. *H. Lehmann*. From Makerere College and Mulago Hospital, Kampala, Uganda. *Africa Lancet* 1: 90-95, 1949

This article contains some interesting observations which help to disentangle some of the problems of both tropical macrocytic anemias and Kwashiorkor.

By the study of 44 cases of severe anemia, the author shows that macrocytosis in the Central African is due mainly to reticulocytosis in response to blood loss or following appropriate treatment. These macrocytes he calls coctics (unfinished) cells being distinct from macrocytes derived from megaloblasts. Most of the patients had a severe hypochromic type of anemia due to hookworms but malaria and infection in some masked the blood picture of iron deficiency. Evidence is given that either iron or worming will give a partial remission in hookworm anemia but that both are necessary for full recovery. It was further noted that worming reversed symptoms usually associated with Kwashiorkor, e.g., pale skin and hair, in patients whose iron deficiency has been corrected. The suggestion is made that the parasites inhibit tyrosine oxidation, thus affecting melanin formation and arresting maturation of reticulocytes. This might be an additional factor in producing macrocytes. Tests in which tyrosine was injected into the skin are described to support the idea of inhibition of oxidation by parasites.

A CASE OF FERNICIOUS FORM ANEMIA IN A CHILD NINETEEN MONTHS OLD. *P. H. D. Waagstein*. From the Medical Service of the County Hospital, Maribo, Denmark. *Acta med Scandinav* 131: 347, 1948

The child had been breast fed until 10 months old. Then for four months chiefly breast fed. Later milk but practically no egg, fish or meat. At 19 months, severe megalocytic anemia with megaloblastic marrow was found. Gastric acidity over 40 units of free HCl after histamine. Treatment with concentrated liver extract gave reticulocyte response and prompt changes in the sternal marrow. After thirty days the red cell count was 4 million. Specific treatment was stopped and after six months there was a severe relapse. Liver extracts had excellent effect again. The diet in the interval was regarded as sufficient.

J.W.

A CASE OF REFRACTORY ANEMIA IN A FINAL STATE SUGGESTIVE OF APLASTIC ANEMIA WITH INCREASED PIGMENTATION OF THE SKIN SUCCESSFULLY TREATED WITH FOLIC ACID. *B. Andersson*. From the Medical Department of the Caroline Hospital in Stockholm. *Acta med Scandinav* 130: 468, 1948

A case of chronic liver refractory macrocytic anemia with nonmegaloblastic marrow and no increase in reticulocytes, no signs of liver damage and presence of free HCl in the gastric juice was treated with blood transfusions until folic acid could be given. With 25 mg. of this preparation *pro die* there was rapid improvement with marked reticulocytosis and increase in both red and white cells. Such cases are of great importance as folic acid seems to be the only way of treating them effectively. The presence of free

HCl in the gastric contents in such atypical liver refractory conditions that respond well to the administration of folic acid should be especially stressed (cf also macrocytic anemia of pregnancy)

J W

ON THE PRICE JONES CURVE IN INITIAL PERNICIOUS ANEMIA *G Tetterman* Helsingfors Acta med Scandinav 129 478 1948

Thirteen patients with initial pernicious anemia were investigated with regard to skewness of the Price Jones curves. The majority of the cases had symmetric curves but the distribution range of the cell-sizes was abnormal showing the blood to be pathologic

J W

PORPHYRIN IN PERNICIOUS ANEMIA *C D De Langen* Medical University Clinic, Utrecht (Holland) Acta haematologica 1 93-98 1948

Liver extracts contain a substance that can combine with porphyrin. The porphyrinic properties are lost as long as it forms part of this compound. This hitherto unknown substance is found especially in the liquid obtained by expression of the liver. In pernicious anemia it is lacking. In urine and stomach secretion of normal persons this substance is always present but in urine and stomach of patients with pernicious anemia it was not found even after treating these patients with liver extracts

C M

FOLIC ACID IN THE TREATMENT OF PERNICIOUS TAPEWORM ANEMIA *B von Bonsdorff* Helsingfors Finland Acta med Scandinav Suppl 213, 81-90 1948 Studia in Honorem Einar Meulengracht

This paper is a continuation of Bonsdorff's previous work on the mechanism of tapeworm anemia in Finland. Folic acid had an excellent effect in four cases of this disease when given in doses of 20-30 mg perorally for 7-10 days. The author concludes that the antianemic effect is not impaired by the presence of the worm in the intestinal canal

J W

DOES FEEDING OF DIPHYLLOBOOTHRIUM LATUM INFLUENCE THE INTERACTION BETWEEN THE INTRINSIC AND THE EXTRINSIC FACTORS OF CASTLE? *B von Bonsdorff* Helsingfors Acta med Scandinav 129 59 1947

The possibility that the tapeworm might contain some substance antagonistic to the action of the antianemic factor formed by the interaction of Castle's intrinsic and extrinsic factors was tested by the author. Neither fresh nor dried tapeworm has any influence on this interaction in vivo. Nor was the remission after the expulsion of the worm checked by peroral administration of dried tapeworm. Preparations of hog's stomach mixed with large amounts of dried worm had retained their therapeutic effect

J W

IN WHICH PART OF THE INTESTINAL CANAL IS THE FISH TAPEWORM FOUND? *B von Bonsdorff* Helsingfors Finland Acta med Scandinav 129 142 1947

The explanation of the fact that only a low percentage of tapeworm carriers show signs of pernicious anemia is not yet found. The possibility that the location of the worm may be of importance from the point of view of pernicious anemia was investigated. It was found that the worm is most frequently located in the ileum rarely in the jejunum and very rarely in the gall bladder. Vomiting of the tapeworm seems to be connected with a higher incidence of anemia. The possibility that the tapeworm may be located higher up in the intestinal canal when vomited seems worth discussing. The author is very careful however in drawing any conclusions regarding the connection between high location of the worm and occurrence of tapeworm anemia

J W

ON THE SECRETION OF GASTRIC JUICE IN RECOVERY AFTER PERNICIOUS BOTHRIOCEPHALUS ANEMIA *C A Hernberg* From the Medical Department of Maria Hospital Helsingfors Acta med Scandinav 129 12, 1947

A follow up examination of 24 patients who had suffered from pernicious tapeworm anemia 1-22 years ago is published. The blood picture was normal. Achlorhydria was found in 11 cases. In all of these

the worm had been expelled only 2-3 years ago. In the other cases 7-9 years had elapsed since the expulsion of the worm. No case was found where an idiopathic pernicious anemia had developed.

## ANEMIA THERAPEUTIC AGENTS

THYMIDINE AND VITAMIN B<sub>12</sub> IN PERNICIOUS ANEMIA. C C Ungley. From the Royal Victoria Infirmary, Newcastle upon Tyne, England. *Lancet* 1: 164-165, 1949.

Thymidine has been isolated from liver and found to prevent the toxicity of methyl folic acid. It can also replace vitamin B<sub>12</sub> in the nutrition of certain lactobacilli. Such microbiologic evidence suggested that thymidine might have antipernicious anemia activity.

This paper reports that 48 mg. of thymidine intramuscularly produced no hematologic remission in a patient with classic Addisonian pernicious anemia. The same patient later responded to 7.5 µg. of a red crystalline antipernicious anemia factor identical with or closely allied to vitamin B<sub>12</sub>.
